Abstract. Despite their potential as a valuable source of individual turbine power performance and turbine array energy production optimization information, nacelle-mounted anemometers have often been neglected because complex flows around the blades and nacelle interfere with their measurements. This work quantitatively explores the accuracy of and potential corrections to nacelle anemometer measurements to determine the degree to which they may be useful when corrected for these complex flows, particularly for calculating annual energy production (AEP) in the absence of other meteorological data. Using upwind meteorological tower measurements along with nacelle-based measurements from a General Electric (GE) 1.5sle model, we calculate empirical nacelle transfer functions (NTFs) and explore how they are impacted by different atmospheric and turbulence parameters. This work provides guidelines for the use of NTFs for deriving useful wind measurements from nacelle-mounted anemometers. Corrections to the nacelle anemometer wind speed measurements can be made with NTFs and used to calculate an AEP that comes within 1 % of an AEP calculated with upwind measurements. We also calculate unique NTFs for different atmospheric conditions defined by temperature stratification as well as turbulence intensity, turbulence kinetic energy, and wind shear. During periods of low stability as defined by the Bulk Richardson number (R_B), the nacelle-mounted anemometer underestimates the upwind wind speed more than during periods of high stability at some wind speed bins below rated speed, leading to a more steep NTF during periods of low stability. Similarly, during periods of high turbulence, the nacelle-mounted anemometer underestimates the upwind wind speed more than during periods of low turbulence at most wind bins between cut-in and rated wind speed. Based on these results, we suggest different NTFs be calculated for different regimes of atmospheric stability and turbulence for power performance validation purposes.

1 Introduction

Traditionally, each wind turbine has an anemometer and wind vane mounted on its nacelle, behind the hub (Fig.1).

Measurements collected from these instruments are used for yaw control and turbine cut-in/cut-out procedures.

30 Nacelle measurements could also be used to help improve turbine or park efficiency. For example, power
performance verifications for individual turbines can now be based on the nacelle anemometer with suitable nacelle
transfer functions (NTFs) (International Electrotechnical Commission [IEC] 61400-12-2 2013). Nacelle
measurements can also provide critical input for wind farm production optimization (Fleming et al., 2016). With
sufficiently accurate NTFs, these data can provide a valuable, extensive, and continuous source of turbine-specific
35 performance information.

Figure 1. GE-1.5/77 sle turbine at the National Wind Technology Center. Photo credit: Dennis Schroeder/NREL (image gallery number 29611).

Power performance validation has traditionally relied on hub-height wind speed observations from a meteorological (met) tower upwind of a turbine (Link and Santos, 2004; IEC 61400-12-1, 2015). The IEC 61400-12-1 (2015) standards require a met tower to be placed at the turbine location prior to turbine erection (the so-called “site calibration” procedure) for a power performance test to be considered valid (of sufficiently low total uncertainty) in complex terrain. However, it is not feasible to erect “site calibration” met towers after the turbine has been erected. And, even if “site calibration” is not required because a site is in simple terrain, tower erection is time-consuming and unrealistic to complete for every turbine at a given park. These factors motivate exploration of the use of nacelle-mounted anemometers to provide wind speed data for power performance validation.

Several studies have found that nacelle anemometer measurements can be adjusted by the use of transfer functions between some upwind hub-height measurement and the nacelle-mounted anemometer measurement (Antoniou and Pedersen, 1997; Hunter et al., 2001, Smith et al., 2002; Smaïli and Masson, 2004). The IEC 61400-12-2 (2013) standard now allows the use of nacelle-mounted anemometers to verify power curves based on these transfer functions, or fitted functions of correction factors between upwind hub-height wind speed (UHWS) measurements and nacelle-mounted anemometer wind speed (NAWS) measurements. Quantifying these transfer functions require upwind measurements be available at some point post-construction. However, once transfer functions are calculated for a site, the tower can be taken down and the transfer functions used to correct the nacelle measurements for future performance testing.

An empirical NTF may not result in a linear relationship between the UHWS and NAWS. In fact, Antoniou and Pedersen (1997) found that the transfer functions fit well with a fifth-order polynomial curve. Hunter et al. (2001) similarly found a non-linear relationship and that a linear regression would overestimate the wind speed between 6 and 11 m s^{-1} and underestimate the wind speed at wind speeds less than 4 m s^{-1} and greater than 16 m s^{-1} . Smith et al. (2002) found a linear relationship with the exception of wind speeds below cut-in and wind speeds about 15 m s^{-1} .

In previous work, the relationship between UHWS measurements and NAWS measurements has been found to depend on multiple factors, including rotor and turbine control settings such as blade pitch angle and inflow angle, the use of vortex generators, yaw error, terrain, flow induction, calibration of the anemometer, and nacelle

height and position (Antoniou and Pedersen, 1997; Dahlberg et al., 1999; Smith et al., 2002; Smaïli and Masson, 2004; Frandsen et al., 2009; Zahle and Sørensen, 2011).

65 The roles of inflow turbulence and atmospheric stability on NTFs have not yet been explored. However, previous work on power performance and annual energy production (AEP) does acknowledge the role of atmospheric stability, wind shear, and turbulence intensity (TI) in inducing deviations of power from the manufacturer power curve (MPC) (e.g., Sumner and Masson, 2006; Antoniou et al., 2009; Rareshide et al., 2009; Wagenaar and Eecen, 2011; Wharton and Lundquist, 2012; Vanderwende and Lundquist, 2012; St. Martin et al., 70 2016).

In this study, we quantify the effect of NTF-corrected nacelle anemometer measurements on the AEP and investigate the influence of different atmospheric stability and turbulence regimes on these NTFs. In Sect. 2, we briefly summarize our data set, which includes upwind and nacelle-based measurements, as well as our data analysis methods which include filtering based on turbine operation, and definitions of the stability and turbulence regimes. 75 We present results of AEP calculations together with results of separate NTFs for different stability and turbulence regimes in Sect. 3. In Sect. 4 we summarize conclusions about the effect of the NTF on the AEP in addition to the effects of atmospheric stability and inflow turbulence on the NTFs.

2 Data and methods

2.1 Meteorological and turbine data

80 For this analysis, we use 2.5 months of data collected at the U.S. Department of Energy (DOE) National Wind Technology Center (NWTC) at the National Renewable Energy Laboratory (NREL) during the wintertime (29 November 2012–14 February 2013). Ten-minute-averaged turbine supervisory control and data acquisition (SCADA) data used in this study are from a General Electric (GE)-1.5-MW turbine (GE-1.5/77 sle, Fig.1), with a cut-in wind speed of 3.5 m s^{-1} , rated wind speed of 14 m s^{-1} , and cut-out wind speed of 25 m s^{-1} . A map of the site 85 can be found in St. Martin et al. (2016) (Fig. 1). See Mendoza et al. (2015) for power performance test results from the DOE GE-1.5 along with instrument and site calibration information.

Upwind data include 1-Hz measurements of wind speed and direction averaged to 10 min from a Renewable NRG Systems (NRG)/LEOSPHERE WINDCUBE v1 vertically profiling Doppler lidar (2.7 rotor

diameters (D) upwind; 208 m) and 10- and 30-min averages from a 135-m met tower (2.0 D upwind; 154 m).

Volumetric-averaged wind speeds and directions are measured by the lidar every 20 m, from 40 m to 220 m. Comparison of the lidar wind profiles to those from the met tower suggest that the lidar data at this site suffered from inhomogeneities as a result of complex flows (Bingöl et al., 2009; Rhodes and Lundquist, 2013; Lundquist et al., 2015), and so the majority of this paper will focus on the results of the analysis using the tower data. On the met tower, cup anemometers placed at 3, 10, 30, 38, 55, 80, 87, 105, 122, and 130 m measure wind speed, vanes placed at 3, 10, 38, 87, and 122 m measure wind direction, and three-dimensional (3-D) sonic anemometers placed at 15, 41, 61, 74, 100, and 119 m measure all three components of the wind as well as sonic temperature which are used to calculate momentum and heat fluxes (Table 1). Barometric pressure and precipitation amounts are measured at 3 m, temperature is measured at 3, 38, and 87 m, and dew point temperature is measured at 3, 38, 87, 122 m (Table 1). See Fig. 2 in St. Martin et al. (2016) for a schematic of the tower.

Table 1. 135-m met tower instrument mounting heights.

Instrument	Mounting heights (m)
Cup anemometer	3, 10, 30, 38, 55, 80, 87, 105, 122, 130
Wind vane	3, 10, 38, 87, 122
3-D sonic anemometer	15, 41, 61, 74, 100, 119
Barometric pressure sensor	3
Precipitation sensor	3
Temperature sensor	3, 38, 87
Dew point temperature sensor	3, 38, 87, 122

As discussed in St. Martin et al. (2016), meteorological and turbine data are filtered for quality assurance. Data are only considered during time periods when the turbine is operating and wind direction indicates the turbine is located downwind of the lidar and met tower (235° – 315°). As the turbine data from the SCADA system is available in 10-min increments, variability of the turbine parameters on a shorter timescale cannot be discerned. However, we filter for “normal turbine operation” based on curtailment using generator speed set point for wind

speeds greater than 5.5 m s^{-1} , whereas for wind speeds less than 5.5 m s^{-1} , we discard data when the turbine is not grid-connected and is faulted (Fig. 6 in St. Martin et al., 2016).

Lastly, the nacelle-reported wind speeds used in this analysis have been subjected to a simple, linear regression transfer function before the retrieval from the SCADA system of the DOE GE 1.5 sle turbine. This linear regression function, built into the SCADA system by the turbine manufacturer, effectively translates the raw signal from the cup anemometer to wind speed and is not unlike a transfer function provided by an anemometer manufacturer. We see the uncertainty of this built-in transfer function as an advantage to our analysis as a typical wind plant operator would only have access to similar data.

2.2 AEP calculations

To simulate a scenario in which a wind plant operator only has nacelle-based measurements and no upwind tower or remote-sensing measurements, we calculate an AEP (as described in Sect. 9.3 of IEC 61400-12-2, 2013) using only nacelle winds to compare to an AEP calculated with upwind met tower 80-m winds. We then correct the nacelle-based measurements with NTFs and calculate AEP based on these results for comparison as well. Although data for this analysis only spans 2.5 months in the wintertime at the NWTC during the 2012–2013 season, we calculate AEPs using the total amount of hours in an entire year to show values close to a representative AEP value. A sample wind distribution using Weibull distribution parameters representative of the data set (scale parameter: $\lambda = 10.04 \text{ m s}^{-1}$, shape parameter: $k = 2.63$, figure not shown) is used in these calculations as suggested by IEC 61400 12-1 (2015) for a site-specific AEP. We note that these parameters, based on 2.5 months in the “high” wind season at this site, are not actually representative of the entire year. However, as noted in other analyses of this test site (Clifton and Lundquist, 2012; Clifton et al., 2013), this site would not be chosen for wind development given the long summer season with little or no wind. We emphasize that this approach is not meant to suggest actual AEPs for this site, but to explore the sensitivity of AEP calculations at sites reasonable for wind development.

2.3 Stability metrics

We calculate Bulk Richardson number (R_B), Obukhov length (L), and the power law exponent (α) and use these as stability metrics for these data. Using wind speed and temperature differences between surface and upper tip (3 m

and 122 m, respectively) tower measurements, we calculate 10-min values of R_B to compare the buoyant production of turbulence to the mechanical production of turbulence (Stull, 1988) as

$$R_B = \frac{g\Delta T\Delta z}{\bar{T}\Delta U^2} , \quad (1)$$

135 where g is the gravitational constant, ΔT is the change in temperature across Δz , \bar{T} is the mean temperature across Δz , and ΔU is the change in horizontal wind speed across Δz . Humidity is not considered in this formulation of the Bulk Richardson number.

Using near-surface flux measurements at 15 m (within the surface layer) as well as surface temperature and humidity measurements linearly interpolated to 15 m, we calculate 30-min values of L to estimate the height at
140 which the buoyant production of turbulence dominates the mechanical production of turbulence (Stull, 1988) as

$$L = -\frac{u_*^3}{kg} \frac{T_v}{w'T_s'} , \quad (2)$$

where u_* is the friction velocity, k is the von Kármán constant, T_v is the virtual temperature, w' is the vertical wind speed fluctuation, and T_s' is the sonic temperature fluctuation.

Using horizontal wind speeds as measured by cup anemometers at 38 m and 122 m (lower tip and upper tip
145 of the rotor disk), we calculate 10-min values of α to quantify the wind speed vertical profile across the rotor disk as

$$\alpha = \frac{\log \frac{U_2}{U_1}}{\log \frac{z_2}{z_1}} , \quad (3)$$

where U_2 is the wind speed at height z_2 and U_1 is the wind speed at height z_1 .

Though some previous studies combine metrics to define stability (Vanderwende and Lundquist, 2012), the three atmospheric stability metrics discussed here are treated separately with regard to the NTFs because of slight
150 differences between their definitions of unstable and stable conditions (see Fig. 11 in St. Martin et al., 2016). These differences may be attributed to distinctions between each approach in defining atmospheric stability, a difference in averaging period, heights of the measurements used in the calculations, or how R_B and L use wind speed and temperature measurements to define stability, whereas α uses only wind speed measurements.

Further, we calculate TI and turbulence kinetic energy (TKE) to provide turbulence metrics and estimate the effect of hub-height inflow turbulence on the NTFs. Using 80-m wind speed measurements from the met tower, we calculate 10-min values of TI, or the standard deviation of the horizontal wind speed normalized by the average horizontal wind speed at hub height. Using 74-m wind measurements from a 3-D sonic anemometer on the tower, we calculate 30-min values of TKE per unit mass, or the sum of the variances of the components of the wind divided by two. Note that after filtering out spikes in the raw 74-m sonic anemometer data, only about 367 thirty-min TKE values remain (183.5 h) and the fewer number of data points likely affects the statistical significance of the NTFs for different TKE regimes. Regimes of TI, TKE, and α are determined by splitting the distributions of each parameter roughly into thirds. Regimes of R_B are similarly determined, as in Aitken et al. (2014) and St. Martin et al. (2016), and uncertainty in the R_B values calculated from propagation of instrument accuracy ensures the regimes are wide enough. Stability regimes based on L are similar to those defined by Muñoz-Esparza (2012). Regimes or classifications for these stability and turbulence parameters are defined in Table 2 and described in detail in St. Martin et al. (2016), along with more detailed descriptions of the data from the lidar, tower and turbine, as well as filtering methods.

Table 2. Defined stability and turbulence regimes.

Regime	R_B	L (m)	α	TI (%)	TKE ($\text{m}^2 \text{s}^{-2}$)
Low	$R_B < -0.03$	$-1,000 < L \leq 0$	$\alpha < 0.11$	TI < 15	TKE < 3.0
Medium	$-0.03 < R_B < 0.03$	$0 \leq L < 1,000$	$0.11 < \alpha < 0.17$	$15 < \text{TI} < 20$	$3.0 < \text{TKE} < 6.5$
High	$R_B > 0.03$	$ L \geq 1,000$	$\alpha > 0.17$	TI > 20	TKE > 6.5

3 Results

To explore the variability of the NTF, we calculate specific NTFs filtered by atmospheric stability metrics, TI, and TKE. We investigate filters that have either previously been found to affect the transfer function or are suspected to have an effect on the transfer functions based on power curve studies (e.g., St. Martin et al., 2016). Additionally, we explore the effects of yaw error and wind veer and distributions of these variables, but, as in St. Martin et al. (2016), yaw error and wind veer do not seem to impact either the power curves or the NTFs at this site and therefore are not shown.

175 3.1 Preliminary NTFs

A general NTF (Fig. 2a) compares the tower 80-m wind speed to the nacelle-reported wind speed using all data that pass the wind speed, wind direction, and normal operation criteria defined in Sect. 2.1 and in more detail in Sect. 3.2 and 3.3 in St. Martin et al. (2016). As a fifth-order polynomial fit was found to be suitable for power curve assessment in previous work by Antoniou and Pedersen (1997) and Hunter et al. (2001), we also apply this type of fit to the wind speeds in this work to estimate an empirical transfer function between 80-m tower wind speed measurements and nacelle-mounted anemometer wind speed measurements (Fig. 2a). The r-squared value of the fifth-order polynomial fit to the data is 0.9912, which means the fit line predicts 99.12% of the variance in the tower data. The root-mean-square error (RMSE) of the fifth-order polynomial fit is 0.3615 m s^{-1} . After correcting the nacelle-measured wind speeds using this NTF, deviations between the corrected nacelle wind speed and the tower 80-m wind speeds (Fig. 2b) vary between -0.2 and 0.2 m s^{-1} throughout all wind speed bins between cut-in and cut-out wind speed.

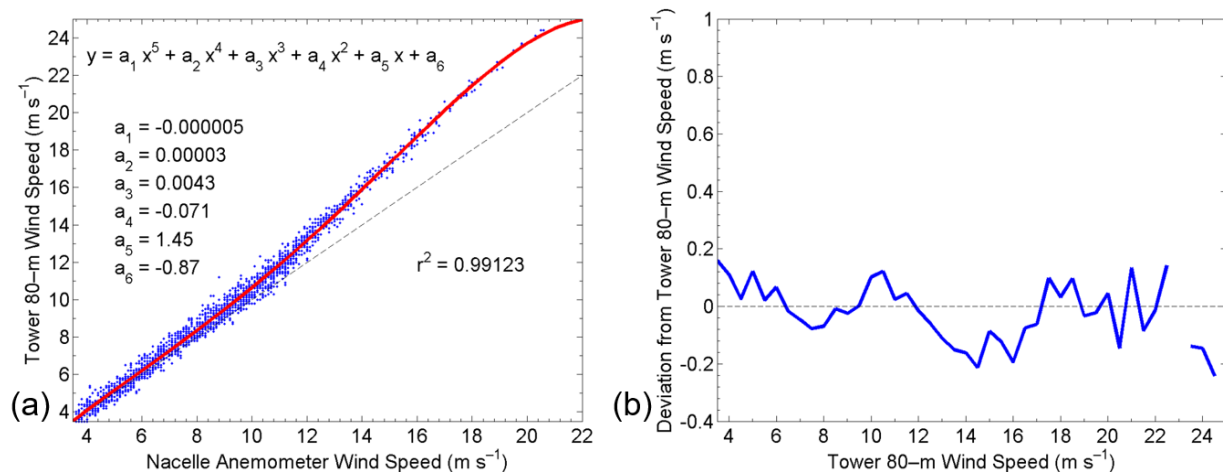

Figure 2. Comparison of upwind wind speeds with nacelle anemometer wind speeds: (a) Scatter is the upwind tower 80-m wind speed versus nacelle wind speed. Red line is the fifth-order polynomial fit and empirical transfer function between the tower 80-m observations and the nacelle-mounted anemometer observations. Dashed line is 1:1. (b) Average deviation in fifth-order polynomial nacelle transfer function (NTF)-corrected nacelle-mounted anemometer wind speed from tower 80-m wind speed versus tower 80-m wind speed. The dashed line indicates a 0 m s^{-1} change. The figure includes data filtered for the tower 80-m wind speeds between 3.5 and 25.0 m s^{-1} , 87-m wind directions between 235° and 315° , and for normal turbine operation.

Based on the small coefficients of the third-, fourth-, and fifth-order of the fit in Fig. 2a, a fifth-order polynomial may be unnecessarily complex. Therefore, a second-order polynomial fit is also calculated to estimate an empirical transfer function. The r-squared value of the second-order polynomial fit with the data is also very high, 0.9909 (Fig. 3a). The RMSE of the second-order polynomial fit is 0.3680 m s^{-1} . After correcting the nacelle-measured wind speeds using this NTF, deviations between the corrected nacelle wind speed and the tower 80-m wind speeds, shown in Fig. 3b, vary from about -0.3 to 0.2 m s^{-1} at wind speed less than about 22 m s^{-1} but grow to about 0.8 m s^{-1} at higher wind speeds. Though there are fewer data points at these higher wind speed bins, this larger deviation of the second-order NTF-corrected wind speeds from the upwind wind speeds at higher wind speeds suggests that a fifth-order polynomial NTF is unnecessary until high wind speeds are considered.

Both transfer functions for this dataset (Fig. 2a, Fig. 3a) are close to linear at low wind speeds but non-linear just before rated speed (14 m s^{-1}), hence the higher-order polynomial fits. This behavior suggests that at wind speeds below about 9 m s^{-1} , the nacelle anemometer measurement closely corresponds to the upwind wind speed. Above this wind speed threshold, however, the nacelle anemometer underestimates the upwind wind speed by almost 2 m s^{-1} around rated speed to about 4 m s^{-1} at upwind wind speeds near 20 m s^{-1} ; higher ambient wind speeds are associated with more significant slow-downs around the nacelle.

Figure 3. Comparison of upwind wind speeds with nacelle anemometer wind speeds. The red line in (a) is the second-order polynomial fit and empirical transfer function between the tower 80-m observations and the nacelle-mounted anemometer observations and the gray line in (a) is the fifth-order polynomial fit. (b) Average deviation in the second-order polynomial NTF-corrected nacelle-mounted anemometer wind speed from tower 80-m wind speed versus tower 80-m wind speed is shown.

Comparison of the NTF developed from the upwind tower measurements and the NTF developed from the upwind lidar measurements (Fig. 4a) emphasizes that the lidar measurements exhibit greater variability ranging over all relevant wind speeds. The variability in the lidar measurements caused by the inhomogeneity of the flow suggests that the tower measurements are more reliable for calculating power curves and transfer functions at this particular site, which is known to experience complex and inhomogeneous flow (Aitken et al., 2014). Despite the larger variability in the lidar data set for both the transfer function (Fig. 4a) and deviations between the corrected nacelle wind speed and the upwind wind speeds (Fig. 4b), both transfer functions in Fig. 4a show linearity at lower wind speeds and non-linearity at higher wind speeds.

Figure 4. (a) NTFs calculated employing fifth-order polynomial fits using tower hub-height data (green) and lidar hub-height data (blue). Envelopes represent $\pm \sigma$ of the data within the same bins as the bins the NTFs are calculated with. Includes data filtered for tower 80-m wind speeds between 3.5 and 25.0 m s⁻¹, 87-m wind directions between 235° and 315°, and for normal turbine operation. Dashed line is 1:1; (b) shows the average deviation in NTF-corrected nacelle-mounted anemometer wind speed from tower 80-m wind speed (green) and lidar 80-m wind speed (blue) versus tower 80-m wind speed. Dashed line indicates a 0 m s⁻¹ change.

To try to quantitatively explain this change in the transfer function from linear to non-linear and to connect with possible flow blockage behind the rotor and along the nacelle, the non-dimensional Froude number (Stull, 1988) for flow around the nacelle is calculated. Froude numbers are investigated during stable conditions using measurements from the tower at the surface and around hub height and using a range of length scales from 1–10 m to represent the length and width of the nacelle. However, distinctions between these two wind speed regions could

not be seen in these calculations as Froude numbers were found to be positive and increase with increasing wind speed.

Additionally, because the transfer functions become non-linear between cut-in wind speed and rated speed, the transfer function may be impacted by turbine operations in that region of the power curve possibly because of root vortices (Whale et al., 2000). Just below rated speed, the blades begin to pitch forward to maintain rated generator speed, thus allowing power production to remain near rated power (Fig. 5). This “feathering” of the blades changes the flow around the blades and therefore the wind that affects the nacelle-mounted anemometer measurement. Though this hypothesis cannot be further investigated within this campaign as higher resolution data from the SCADA system are unavailable, this does make a compelling argument for installing 3-D sonic anemometers on nacelles so vertical velocity can be measured to further understand the 3-D wind structures behind the rotor and along the nacelle, and how these flow structures change as inflow wind speed increases.

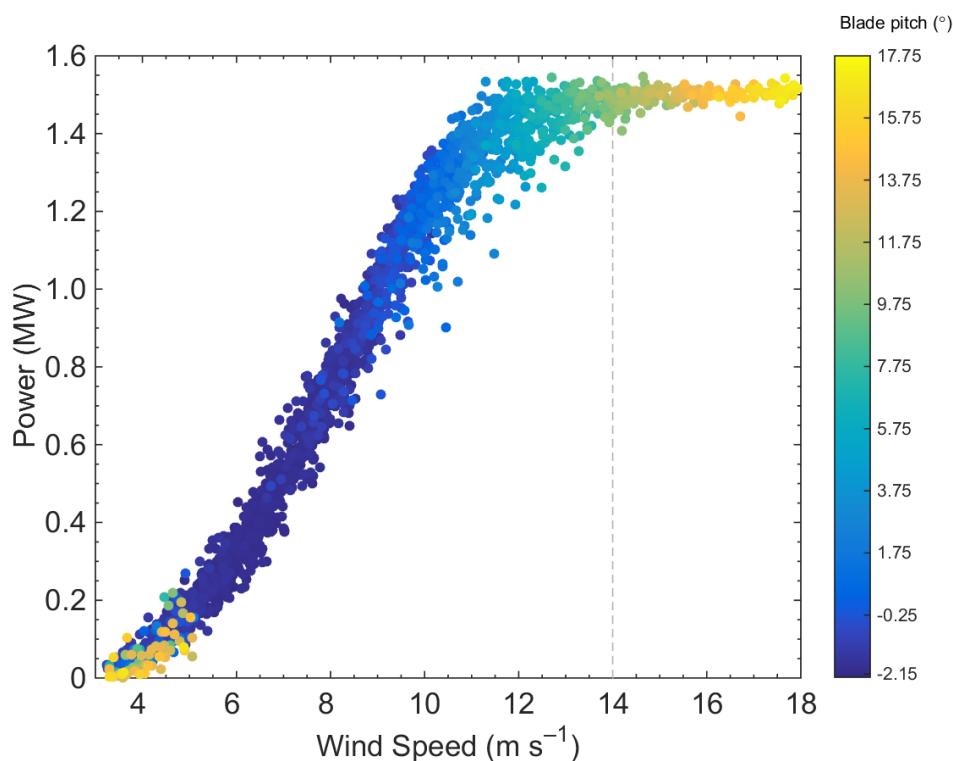

Figure 5. Scatter power curve using 80-m tower winds after filtering for wind speeds between 3.5 and 25 m s⁻¹, wind directions between 235° and 315°, and for normal turbine operation. Colors of the scatter points correspond to blade pitch angles. The grey dashed line marks rated speed.

3.2 Annual energy production and NTFs

It is important to understand the characteristics of the NTF and how it changes with wind speed, as this under-estimation of the ambient wind speed, especially at wind speeds in which the growth in power production with wind speed is the most significant, could result in a significant overestimation of AEP in power performance verification.

With no NTF correction applied (aside from the transfer function that is built into the SCADA system by the manufacturer), the AEP calculated with nacelle winds (AEP_nacelle) overestimates the AEP calculated with 80-m tower winds (AEP_upwind) by 5.96 % (Table 3). This overestimation of AEP is expected as the nacelle anemometer consistently underestimates the upwind wind speed, which leads to the misrepresentation of higher power output at lower wind speeds, effectively shifting the entire power curve to the left, and therefore leading to a higher AEP.

Table 3. Top row: Annual energy production (AEP) in megawatt-hours/year calculated using upwind tower measurements (AEP_upwind), nacelle winds (AEP_nacelle), corrected nacelle winds using the NTF calculated with a fifth-order polynomial (AEP_NTF5th), and corrected nacelle winds using the NTF calculated with a second-order polynomial (AEP_NTF2nd). Bottom row: AEP in percentage calculated as a percentage of AEP_upwind.

	AEP_upwind	AEP_nacelle	AEP_NTF5 th	AEP_NTF2 nd
AEP (MWh/y)	7,479.3	7,924.7	7,479.1	7,465.8
% of tower winds	100.00	105.96	100.00	99.82

The use of the general NTF to correct the nacelle anemometer measurements reduces the AEP error significantly (Table 3). With the application of the fifth-order polynomial NTF (AEP_NTF5th), AEP_NTF5th underestimates AEP_upwind by only 0.003 %, whereas with the application of the second-order polynomial NTF (AEP_NTF2nd), AEP_NTF2nd underestimates AEP_upwind by 0.18 %. Therefore, using either the fifth-order polynomial or the second-order polynomial for the NTF results in an AEP similar to that of an AEP calculated with upwind hub-height winds; though both lead to a slight underestimation.

3.3 Atmospheric stability effects of NTFs

The value of atmospheric-stability segregation for NTFs seems to depend on how stability is defined. Some statistically significant distinctions in the NTFs for R_B -defined unstable and stable cases do emerge (Fig. 6a, Table 4), particularly for wind speeds between 7 and 11 m s^{-1} . Closed circles in Fig. 6a represent statistically distinct wind speed bins between the stability classes and are determined by the Wilcoxon rank sum test with a 1 % significance level. Stable cases follow a linear relationship more closely for low and moderate wind speeds (less than 11 m s^{-1}), whereas unstable cases show more deviation from the 1:1 line at wind speeds greater than 8 m s^{-1} . This behavior shown by NTFs segregated by R_B suggests that below rated speed in convective conditions, the nacelle anemometer underestimates the ambient wind speed more than in stable conditions. Conversely, no statistically significant distinctions emerge in the NTFs for L -defined stability classes for this site using our dataset (Fig. 7a, Table 4). Distinctions in the NTFs for α -defined cases (Fig. 8a, Table 5) emerge only around 13.5 m s^{-1} —much closer to rated speed—and stable cases underestimate the upwind wind speed more than unstable cases.

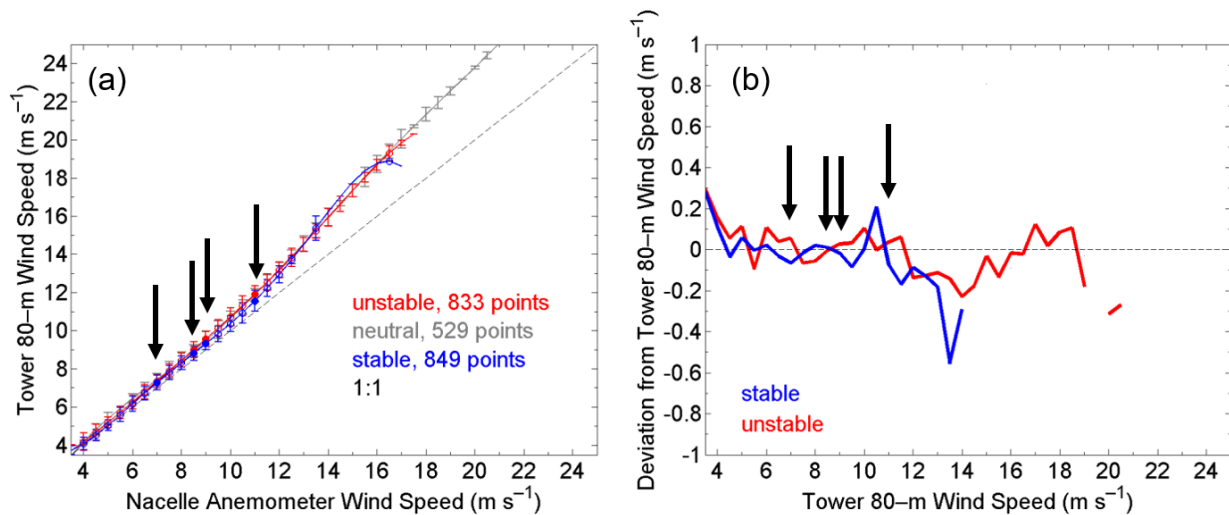

Figure 6. (a) Tower 80-m NTFs calculated using fifth-order polynomial fits with stability regimes based on R_B . Error bars represent $\pm \sigma$ of the data within the same bins as the bins with which the NTFs are calculated. Statistically distinct differences within each wind speed bin between the stability classes are determined by the Wilcoxon rank sum test with a 1 % significance level and denoted by closed circles. Black arrows point towards statistically distinct bins. The figures include data filtered for tower 80-m wind speeds between 3.5 and 25.0 m s^{-1} , 87-m wind directions between 235° and 315°, and for normal turbine operation. (b) Average deviation in NTF-corrected nacelle-mounted anemometer wind speed from tower 80-m wind speed is shown during stable conditions (blue) and during unstable conditions (red) versus tower 80-m wind speed with stability regimes based on R_B . Dashed line indicates a 0 m s^{-1} change.

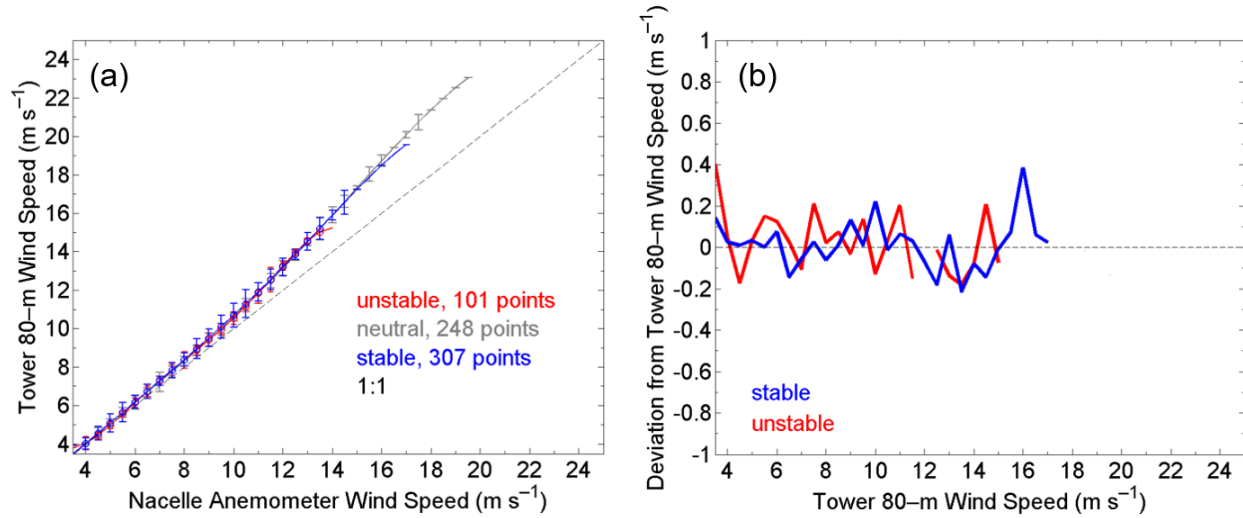

Figure 7. (a) Tower 80-m NTFs calculated using fifth-order polynomial fits with stability regimes based on L . Error bars represent $\pm \sigma$ of the data within the same bins as the bins with which the NTFs are calculated. Statistically distinct differences within each wind speed bin between the stability classes are determined by the Wilcoxon rank sum test with a 1 % significance level and denoted by closed circles. The figures include data filtered for tower 80-m wind speeds between 3.5 and 25.0 m s^{-1} , 87-m wind directions between 235° and 315°, and for normal turbine operation. (b) Average deviation in NTF-corrected nacelle-mounted anemometer wind speed from tower 80-m wind speed is shown during stable conditions (blue) and during unstable conditions (red) versus tower 80-m wind speed with stability regimes based on L . Dashed line indicates a 0 m s^{-1} change.

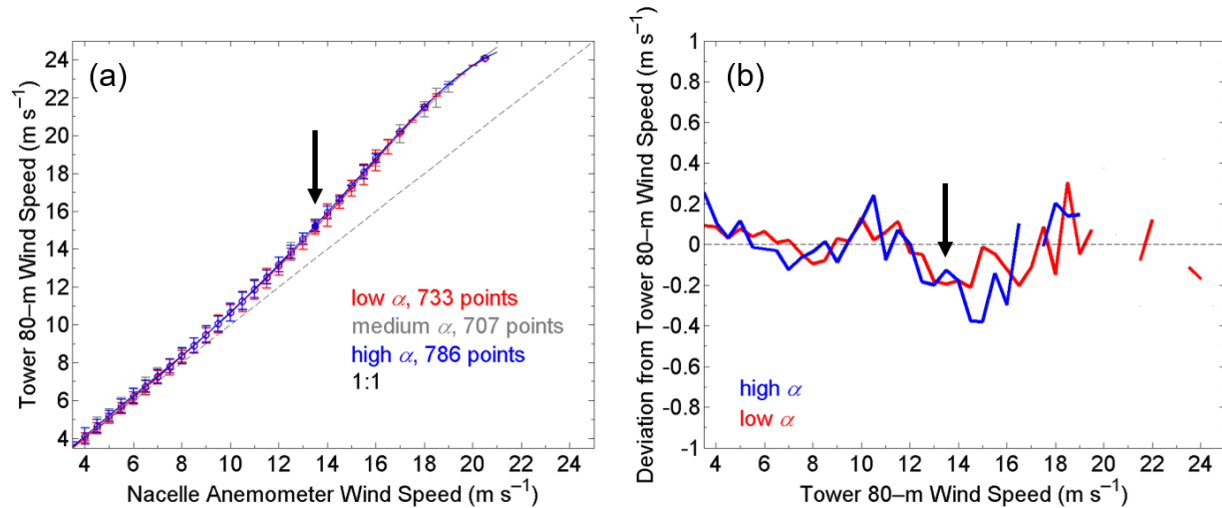

Figure 8. (a) Tower 80-m NTFs calculated using fifth-order polynomial fits with stability regimes based on α . Error bars represent $\pm \sigma$ of the data within the same bins as the bins with which the NTFs are calculated. Statistically distinct differences within each wind speed bin between the stability classes are determined by the Wilcoxon rank sum test with a 1 % significance level and denoted by closed circles. Black arrows point towards statistically distinct bins. The figures include data filtered for tower 80-m wind speeds between 3.5 and 25.0 m s^{-1} , 87-m wind directions between 235° and 315°, and for normal turbine operation. (b) Average deviation in NTF-corrected nacelle-mounted anemometer wind speed from tower 80-m wind speed is shown during stable conditions (blue) and during unstable conditions (red) versus tower 80-m wind speed with stability regimes based on α . Dashed line indicates a 0 m s^{-1} change.

We apply the NTFs to the nacelle anemometer measurements to evaluate the deviations from the upwind met tower data (Figs. 6b, 7b, 8b); however, the results show no consistency or systematic distinctions between stability metrics, stability classes, or wind speed.

290 3.4 Turbulence effects on NTFs

The hypothesis that convectively-driven mixing and turbulence causes underestimation by the nacelle-mounted anemometer is further supported in the NTFs segregated by TI (Fig. 9a, Table 6) and TKE classes (Fig. 9b, Table 6). Distinctions between unstable and stable cases in the transfer functions for wind speeds between 5.5 and 12 m s^{-1} are also apparent when the transfer functions are segregated by TI class (Fig. 9a) and for wind speeds around 12 m

295 s^{-1} when the transfer functions are segregated by TKE class (Fig. 9b). Periods of relatively high TI and TKE result
in greater underestimations of the wind speed by the nacelle anemometer from just above cut-in wind speed to about
300 12 m s^{-1} .

Corrections to the nacelle wind speeds using NTFs based on atmospheric turbulence show lower deviations
from the ambient wind speed below rated speed and larger deviations from the ambient wind speed after rated speed
300 for high TI cases. However, similar to the results in Figs. 6b, 7b, and 8b, Fig. 9c–d also show inconsistencies
between deviations from the upwind speed for the different turbulence metrics and regimes.

Figure 9. Tower 80-m NTFs calculated using fifth-order polynomial fits with turbulence regimes based on (a) turbulence intensity (TI) and (b) turbulence kinetic energy (TKE). Error bars represent $\pm \sigma$ of the data within the same bins as the bins with which the NTFs are calculated. Statistically distinct differences within each wind speed bin between the stability classes are

denoted by closed circles. Figures include data filtered for tower 80-m wind speeds between 3.5 and 25.0 m s⁻¹, 87-m wind directions between 235° and 315°, and for normal turbine operation. Average deviation in NTF-corrected nacelle-mounted anemometer wind speed from tower 80-m wind speed is shown during stable conditions (blue) and during unstable conditions (red) versus tower 80-m wind speed with turbulence regimes based on (c) TI and (d) TKE. Dashed line indicates a 0 m s⁻¹ change.

3.5 Discussion

We speculate that at wind speeds below rated, mixing in the atmosphere during more convective conditions, as well as the turbine interaction with these turbulent eddies, may result in additional motion that exaggerates blockage effects by the rotor and nacelle and causes underestimation by the nacelle-mounted anemometer. We suspect that rotor response is lagging in more convective and turbulent conditions as the turbine responds more quickly to drops in wind speed. Therefore, during more turbulent conditions, it is possible that lower rotor efficiency influences flow induction and thus the wind speeds measured on the back of the nacelle. If turbine and rotor efficiencies are lower during periods with convective and more turbulent conditions, it may be surmised then, that less momentum passes through the rotor and along the nacelle. In addition, power curve results from the same dataset discussed here (St. Martin et al., 2016) show that during less stable and more turbulent conditions at wind speeds within the ramp-up region of the power curve, more power is produced than during periods of more stable and less turbulent conditions. Power production will also affect the flow induction (Frandsen et al., 2009) and thus the wind speed directly behind

the rotor disk: if more energy is extracted by the rotor, the nacelle-mounted anemometer will likely measure lower winds.

4 Conclusions

Over two months of data from both upwind instruments and nacelle-based instruments are used to quantify general nacelle transfer functions (NTFs) as well as NTFs that vary with atmospheric stability and turbulence parameters.

We show that correcting nacelle winds using these NTFs results in more accurate annual energy production (AEP) estimates that are similar to estimates obtained using upwind meteorological (met) tower-based wind speeds.

Further, multiple factors have been investigated for their influence on NTFs, including both parameters known to influence wind power production and parameters never before investigated in the context of transfer functions.

We find that fitting the data to a fifth-order polynomial to estimate the NTF results in a slightly higher r-squared value and smaller root-mean-square error (RMSE) than fitting to a second-order polynomial. The small differences in the uncertainties between the two methods seem insignificant, as the r-squared value of 0.9909 using the second-order polynomial is comparable to the 0.9912 value using the fifth-order fit. However, though the r-squared value of the second-order fit is high, after correcting the nacelle winds with the second-order NTF, larger deviations from the upwind tower winds occur than if a fifth-order NTF is used, especially at higher wind speeds.

At wind speeds below 9 m s^{-1} , the nacelle anemometer measurement closely corresponds to the upwind wind speed measurement. Above this wind speed threshold, however, the nacelle anemometer underestimates the upwind wind speed, which could result in a significant underestimation of power production and could be perceived as turbine over-performance (or mask turbine under-performance) if not corrected for by a NTF. Additionally, the non-linear nature of the transfer functions above 9 m s^{-1} or so suggests that the transfer function may be impacted by turbine operations near rated speed and how they affect the flow behind the rotor disk and along the nacelle.

The use of NTFs in AEP calculations results in a less than 1 % difference from the AEP calculated with the upwind met tower wind speed. AEP calculations reveal that an AEP calculated using a fifth-order polynomial correction to the nacelle winds results in a 0.003 % underestimation of the AEP calculated with the upwind wind speed, whereas an AEP calculated using a second-order polynomial correction results in a 0.18 % underestimation of the AEP calculated with the upwind wind speed. Both are sizeable improvements over using the uncorrected

nacelle wind speed, which leads to a 5.96 % overestimation when compared to the AEP calculated with the upwind wind speed.

Statistically significant distinctions emerge in the transfer functions for unstable and stable cases as defined by the Bulk Richardson number (R_B), particularly for wind speeds between 9 and 11 m s⁻¹. At these wind speeds before rated, in unstable conditions, the nacelle anemometer underestimates the ambient wind speed more often than in stable conditions. Similar but more prominent behavior is found in transfer functions separated by turbulence intensity (TI) and turbulence kinetic energy (TKE) classifications: during periods with relatively high TI and TKE, the nacelle anemometer underestimates the ambient wind speed more than during periods of relatively low TI and TKE, between about 6 and 12 m s⁻¹. We speculate that turbine interaction with the mixing in the atmosphere during more convective and turbulent conditions may result in additional motion, thereby exaggerating the blockage by the nacelle and thus underestimation by the nacelle-mounted anemometer.

Distinctions in power curves (Sumner and Masson, 2006; Antoniou et al., 2009; Vanderwende and Lundquist, 2012; Dörenkämper et al., 2014; St. Martin et al., 2016) can lead to a correlation between these and distinctions in NTFs as well as the idea of validating power performance data with similar atmospheric and operational characteristics with their corresponding power curve in an effort to decrease the amount of uncertainty in power performance testing.

NTFs have recently been accepted for power curve validation under certain circumstances (IEC 61400-12-2, 2013). They can also enable the use of nacelle-mounted anemometers for AEP estimates, turbine performance analysis, and data assimilation for improved forecasting (Draxl, 2012; Delle Monache et al., 2013).

Further work could explore how turbine controls and characteristics such as thrust affect the transfer functions. Simulations of flow around the nacelle such as those of Keck (2012) could be expanded to account for variations in atmospheric stability and could be coupled with control software simulators. As Bibor and Masson (2007) suggest, a single transfer function should not be used for every wind plant site and for every atmospheric and operating condition. Several atmospheric and operational conditions and how they affect the transfer functions should be investigated and perhaps combined to provide an algorithm for manufacturers and wind plant operators to use in power performance validation.

Acknowledgements

The authors express appreciation to the Center for Research and Education in Wind for supporting this work, to Thomas Fischetti and Peter Gregg at GE Renewable Energy for their assistance in turbine data collection and interpretation, and to the reviewers of a previous version of this work. This work was supported by the U.S. Department of Energy under Contract No. DE-AC36-08GO28308 with the National Renewable Energy Laboratory. Funding for the work was provided by the DOE Office of Energy Efficiency and Renewable Energy, Wind and Water Power Technologies Office.
