

Comments for Reviewer 1:

Thank you for the detailed review. It has been difficult to find people to look into the mathematics in detail. I have tried my best to answer your concerns though I am concerned that the written response might not be enough.

I have first gone through the comments on the paper and then responded to your 3 points.

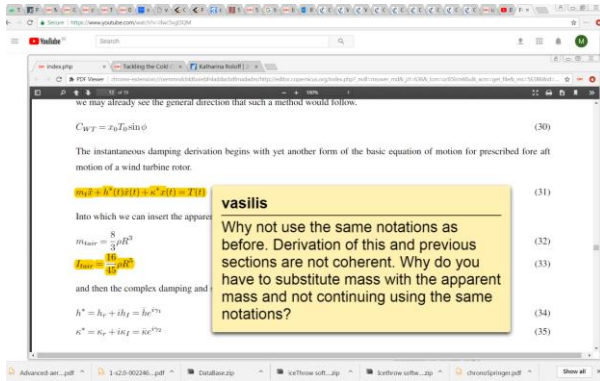

In the case of typos I have corrected without comment. i.e. a missing negative sign or missing -ve infinity.

In this approach, I am prescribing motion in surge direction in this formulation. It is not the same approach as described in Advanced aeroelastic modelling of complete wind turbine configurations. The method is described in detail for the Airfoil undergoing pitching motion by Corke and Bowles. The method derived here is based on theirs.

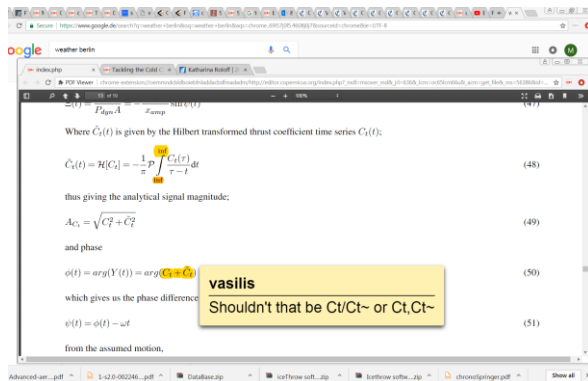

The unfortunate part of the instantaneous damping approach is that you have to re-derive the damping equations for every DOF you want to investigate.

I have clarified in the text to only mention „linearization of the aerodynamics“.

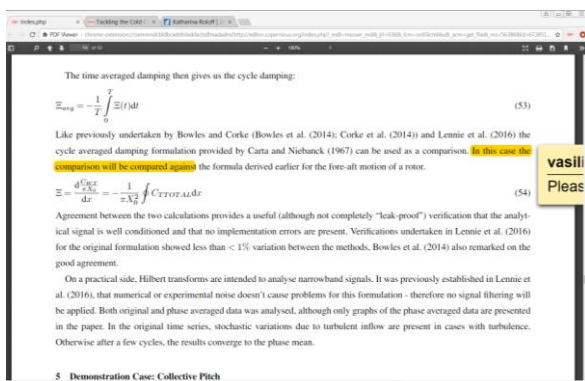

I have consistently used the K^* notation I thought? I checked and found no inconsistency. I used it as a complex variable on two occasions.

The equation appears to represent a mechanical system. It is the aerodynamic system simply using the mechanical analogy of aerodynamic stiffness and damping.

The arg (argument) operator takes care of that.

It was for this verification step among other reasons that I included the previous laborious derivations.

1) I accept your point regarding the derivation. I would like, however, to keep it there. When I first attempted to understand the derivation from Bowles and Corke, it was almost impossible to track what they did until I dug out the old papers. I believe it to be valuable to have all of the derivations

laid out as a solid foundation for the extension that I made, it may be laborious but I think it is very difficult to understand otherwise. Finally, as the journal isn't a print journal with a page limit. I would prefer to leave it there.

However, regarding your suggestion to include another test case I have done this and there is now a new test case looking at the response to a non-harmonic pitch manoeuvre. I hope that this addresses your concern about the 30% extra content.

2) Regarding equations 46-47. I believe the discrepancy comes about because the system I am modelling is not a free response system after initial excitation (which is what I believe your method was?). In this method, the Hilbert transform and analytical system are used to estimate the instantaneous phase between the prescribed motion and the response it produces (in this derivation Thrust force on the rotor). ξ is in fact not periodic because the variables inside the sin function represent the difference between the phase of the prescribed motion and the response again ($\phi(t) - \omega t$). As we are expecting the thrust force to only drag behind the platform translation by a reasonable amount, we can see that $\sin(\phi(t) - \omega t)$ won't be periodic.

3) Regarding the necessity to linearize. Again the prescribed motion means that we are not looking at the structure in any modal sense. One weakness of the current derivation is that I am assuming platform translation as the DOF movement of interest. That doesn't then rely on a linearization but an assumption of a different kind.

If I was to extend this model into modal coordinates then it would be necessary to linearize first. I would then have to perform the modal transform on the aerodynamic terms and that would require the prior knowledge of the modes.

Comments for Reviewer Two:

Thank you for the review.

I have scaled back the excellent agreement.

In absolute terms the spread between the different methods remains about the same. It depends on which part of the cycle you inspect, at the peaks of the harmonic the discrepancies are slightly larger though the effect is minimal.

Modern methods for investigating the stability of a pitching floating platform wind turbine

Matthew Lennie¹, David Marten¹, George Pechlivanoglou¹, Christian Navid Nayeri¹, and Christian Oliver Paschereit¹

Abstract. The QBlade implementation of the Lifting Line Free Vortex Wake method(LLFVW) was tested in conditions analogous to floating platform motion. Comparisons against two independent test cases, using a variety of simulation methods **show good agreement** in thrust forces, rotor power, blade forces and rotor plane induction. Along with the many verifications already undertaken in literature, it seems that the code performs solidly even in these challenging cases. Further to this, the 5 key steps are presented from a new formulation of the instantaneous aerodynamic thrust damping of a wind turbine rotor. A test case with harmonic platform motion and collective blade pitch is used to demonstrate how combining such tools can lead to better understanding of aeroelastic stability. A  case demonstrates a non-harmonic blade pitch maneuver showing the versatility of the instantaneous damping method.

1 Introduction

10 The proliferation of large wind turbine rotors has been accompanied by the need for accurate and computationally inexpensive aeroelastic simulation tools. For aeroelastic simulations, the aerodynamics of the wind turbine are most typically calculated using Blade Element Momentum based methods (BEM). In the scenario of offshore wind, particularly when designing for floating platforms, the significant motion of the rotor leads to complicated aerodynamics. Sebastian and Lackner (2013) have made a convincing case that, even with secondary correction factors, floating platform wind turbine aerodynamics exceed the 15 capabilities of BEM based simulation methods. The main reason being that a floating platform wind turbine will dynamically pitch and yaw. As BEM does not explicitly solve the flow pattern of the wake, it is simply not possible to accurately represent such behaviour.

The Lifting Line Free Vortex Wake method (LLFVW) uses non-linear polar data¹ to calculate the blade forces coupled with a free vortex wake formulation and serves as a good method for simulating cases where large rotor displacements and 20 yaw misalignments occur (see figure 2). Recently, an implementation of a LLFVW code was completed and included in the QBlade wind turbine simulation code (Marten (2015)). Simultaneously to this study, the LLFVW solver is being extended to include an unsteady aerodynamics model² and is being coupled with the structural formulations of the FAST framework

¹Including viscous effects such as separation

²LLFVW formulations inherently account for attached flow unsteadiness, the unsteady aerodynamic model mentioned here only includes terms for detached flow and leading edge vorticity. The details are given by Wendler Wendler et al. (2016)

(Wendler et al. (2016); Saverin et al. (2016)). In this paper, a comparison is made between the LLFVW code and existing literature comparisons where higher order aerodynamic simulation techniques were used i.e. URANS CFD (Tran et al. (2014); Sebastian and Lackner (2013)). The comparisons and further test cases are made using the NREL 5MW reference turbine which is undergoing prescribed harmonic motion (see figure 1)(Jonkman (2013)).

5 After the validation of the LLFVW code for simulations involving a moving rotor plane, the aerodynamic damping of the rotor is investigated. For this analysis, a new formulation is presented for the instantaneous aerodynamic damping of the fore-aft motion degree of freedom. The formulation is a modification of an existing formulation that was first presented by Corke and Bowles (Bowles et al. (2014); Corke et al. (2014)) and later applied by Lennie to an airfoil with microtabs (Lennie et al. (2016)). For the first time, this new formulation makes it possible to look at the aerodynamic damping throughout the pitch
10 cycle of the wind turbine - as opposed to the traditional approach where only cycled averaged values are inspected. Such a formulation is particularly useful for analysing aeroelastic instabilities where limit cycle oscillations are present. Limit cycle oscillations will have cycle averaged values that are neutral but could have occurrences of highly negative damping. Using this method on LLFVW data makes it possible to understand aeroelastic thrust stability of the rotor without the heavy linearisation of the aerodynamics applied in most stability analysis techniques. It is also a useful way of understanding the full effects of
15 controller wind turbine interactions. An example will be presented showing the effect of collective blade pitch cycles during fore-aft motion of the rotor.

2 Rotor Motion

For the scope of this paper, prescribed motion of two varieties are considered. The first variety, pitching, is the more realistic representation where the rotor plane undergoes both pitch and linear translation (see figure 1). The second variety, fore-aft
20 motion, assumes that the rotor plane pitching component is insignificant compared to the influence of the linear translation. Within the scope of this study, investigating the total rotor thrust, the difference between the assumptions is assumed to be small. There may be applications where this assumption is unsuitable. In the comparisons, the same magnitude and type of motion is used as in the literature so that no additional assumptions were introduced.

3 Comparison Cases

25 The QBlade LLFVW implementation has been previously tested for a range of standard HAWT and VAWT cases as can be found in existing literature (Marten (2015); Saverin et al. (2016)). When the wind turbine starts moving relative to the steady inflow, the wake will become distorted. In the case of a harmonic movement, the wake will display harmonic contractions and expansions (see figure 2) which induces velocity onto the rotor plane. The publications mentioned above have focused on verifying the performance of the QBlade LLFVW under stationary conditions and cases with yaw. This means that the battery
30 of verifications undertaken should be extended to include cases where platform motion is present, thus ensuring that LLFVW techniques are a suitable approach for floating platform wind turbine aerodynamics. A number of comparison papers have been

Figure 1. The two different assumed motions for the wind turbine. (Left: wind turbine pitching; Right: wind turbine fore-aft motion)

Figure 2. Snapshot of LLFVW simulation during pitching platform motion; vorticity isosurface of the wake coloured with velocity magnitude

sought from literature that test a horizontal axis wind turbine rotor in prescribed floating platform motion. For the scope of this paper, only rigid body motion will be considered. The comparison will be undertaken by replicating the simulations from literature which used higher order methods.

Two different papers were used as a basis for comparison; both investigating the NREL 5MW reference turbine (Jonkman (2013)). Tran et al. (2014) compares a number of techniques with virtual blade motion using multiple reference frames (CFD-MRF) and real rigid body blade motion (CFD-RBM). The highest order simulation is a 3D Unsteady Reynolds Averaged Navier Stokes (URANS) CFD simulation with a $k-\omega$ shear-stress transport turbulence model. The blade rigid body motion was achieved using an over-set grid which is described at length including a discussion of the mesh convergence. The actual CFD simulations were conducted using commercial codes FluentTM with StarCCM+TM for meshing. It appears from the presented information that the simulations should be high quality, within the limitations of URANS.

Tran et al. (2014) also compared their results against lower order simulations using unsteady blade element momentum method. The Tran et al. (2014) implementation of the unsteady blade element moment method (UBEM) was taken from Hansen (2008) with corrections for tip losses, wake unsteadiness and unsteady aerodynamics. This particular implementation took the platform motion into account by changing the relative inflow velocity. Further comparisons were made using modified versions of FAST(Jonkman (2013)) from the National Renewable Energy Laboratory; one comparison using a momentum balance for the wake solution (FAST-BEM) and the other using generalized dynamic wake (FAST-GDW). In both cases, the structural modes were locked and no controller was used, for more complete details, see the original paper from Tran et al. (2014).

Tran et al. (2014) simulates the pitching of the wind turbine as shown in figure 1(see left hand side). Two cases were simulated with platform pitching amplitudes of 1° and 4° ; and a constant harmonic pitching frequency of 0.1Hz. The calculations were performed at a steady inflow speed of 11m/s with a constant rotational speed of 12rpm and a constant blade pitch angle of 0° . From this paper it was possible to compare thrust, power and integrated blade forces.

The QBlade simulations were run with the same conditions as described above. The unsteady aerodynamic model from Wendler was enabled without vortex lift as the wind turbine is operating at near rated speed without yaw(Wendler et al. (2016)). The standard NREL 5MW model (Jonkman (2013)) was set-up according to the definition³.

The simulation settings can be found in Table 1. The FVLLW requires a number of input parameters which control the behaviour of the wake. The QBlade implementation of FVLLW lumps together wake elements in two stages in order to simulate a full length wake without prohibitive computational costs. The Wake Age, Full Wake and Fine Wake parameters determine the positions where the two stages of wake thinning occur and where the wake is finally truncated. The parameters are described in terms of rotor revolutions to remove the dependency of the parameters on tip speed ratio. The wake thin factor describes the extent to which the wake is thin. The initial vortex core radius is an important parameter for the de-singularisation of the Biot-Savart equation. The turbulent vortex viscosity introduces diffusion to the wake. These parameters should be noted in attempts to reproduce the simulations performed in this paper. The full explanation of each of these parameters can be found in the paper from Marten et al. Marten (2015).

³The standard 5MW project file is available for download with the standard QBlade package

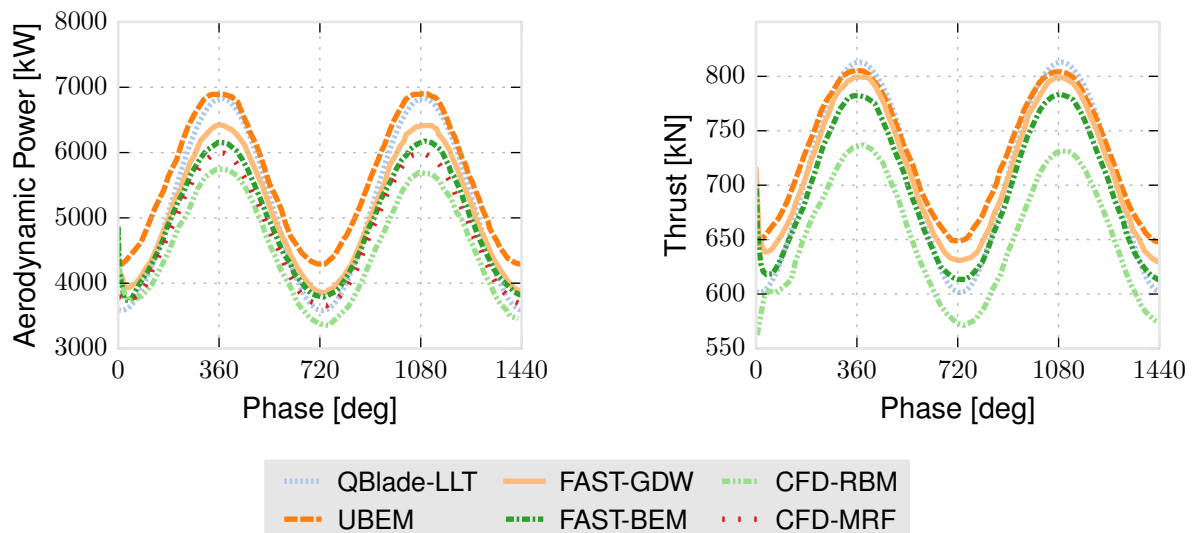

Figure 4. Thrust and power over phase angle for pitching platform motion (1° pitch amplitude) Comparison Case: Tran et al. (2014)

The LLFVW (figure 2) shows moderately good agreement for all cases, which can be seen in figures 3, 4 and 5. It is interesting to note that steady and even unsteady BEM simulations, when compared to CFD or LLFVW results, under predict the magnitude of the load cycle in most cases. The three classes of simulations compared all face limitations. The LLFVW and

Timestep	0.1 Sec

BEM cases both rely on 2D polar data which is sensitive to measurement or simulation settings like wind tunnel turbulence or turbulence model. Lennie et al. (2015) and Eisele et al. (2013) have shown that quality of the 2D polar data is critical for power and loads prediction. For the BEM based methods, it is expected that the empirical corrections will struggle to represent the complicated fore-aft motion. The CFD solutions are based on Unsteady Reynolds Averaged Navier-Stokes (URANS) equations.

5 After conducting thorough verification and validations of multiple URANS solvers with multiple turbulence closure models, Rumsey showed that URANS based models have a very limited ability to model cases with separation (Stangfeld et al. (2015) and Christopher L. Rumsey (2016)). Furthermore, the tendency of URANS codes to smear vorticity will cause errors in the wake induction in the cases where the blades are modeled. With each of the simulation methods facing some sort of limitation, it is difficult to choose one method as the baseline or "most" accurate. Nonetheless, integrated blade forces agree well for the

10 CFD from Tran et al. (2014) and the LLFVW (see figure 5). Discrepancies in thrust and power can be seen in figures 3 and 4, but they are of a reasonable magnitude.

In the publication chosen for a second comparison, Vaal et al. (2014) uses a moving actuator disc CFD hybrid method which allows for a good comparison of the unsteady wake induction between CFD and the LLFVW. The moving actuator disk model essentially places a moveable actuator disk into a CFD simulation (Implemented in FluentTM). In practice this means that the

15 actuator disk acts as a volume force onto the surrounding cells. It is argued by Vaal et al. (2014) that, because this method explicitly solves the wake rather than relying on simplified relations, the method should be more robust than the commonly used methods such as the Pitt-Peters model (Pitt and Peters (1983)) or the Stig-Oye model (Hansen (2008)). Vaal et al. (2014) presents a number of investigations into the relative performance of the models, for this paper, the rotor plane induction is the most interesting to compare.

20 Vaal et al. (2014) undertook a sensitivity study showing the wake velocity before and after the rotor at different phases for different operating conditions. From this study, the authors choose the largest amplitude (16m) of fore-aft movement (right hand side of figure 1). The fore-aft motion was harmonic with a frequency of $0.08Hz$, the inflow speed was 11.2m/s, the blade pitch was 0° and the rotor speed was a constant $0.2Hz$. Vaal et al. (2014) allowed several oscillations to pass in order to let the wake effects develop. The grid extended 10 rotor diameters up and down stream. It would appear that the approach and settings

25 used by Vaal et al. (2014) will provide good quality results for comparison.

The QBlade simulations were conducted again, using the settings stated above, with prescribed linear rotor plane movement. Like Vaal et al. (2014), a number of oscillations were simulated before finally extracting the data. The comparison was made at the exact rotor plane where the axial velocity could be sampled over an area determined by the rotor radius. There was not enough information provided by Vaal et al. (2014) to ensure consistency of the sampling area for the induced velocity. In the context of a wake with expansion and contraction occurring, the assumptions have a distinct effect on the induction results. Therefore, no upstream or downstream comparisons were attempted. A rotor plane axial velocity field snapshot was taken at equally spaced points within the cycle. The results, shown in figure 6, show that the rotor plane induction for the two methods matches well over the four snapshots. It seems therefore that there is a good agreement between the two methods for the most challenging test case presented by Vaal et al. (2014).

From the two verifications performed here it seems that the QBlade LLFVW simulation model produces results that are comparable to other higher order or hybrid methods. These results and the results already published give a high degree of confidence in the simulation tools ability to model wind turbines undergoing platform motion.

4 Using the Hilbert Transform method to obtain instantaneous aerodynamic damping of a translating rotor

The following section briefly outlines a reformulation of the instantaneous damping calculation method outlined by Bowles and Corke (Bowles et al. (2014); Corke et al. (2014)). The original reference by Bowles et al. (2014) describes the original method in complete detail and Lennie et al. (2016) provides an application of the method to an airfoil with microtabs and gurney flaps. In the reformulation described here, the instantaneous damping calculation is applied to the fore-aft motion of the whole rotor, a situation particularly interesting for floating platform wind turbines. It is assumed for this paper that a small pitch angle means that the linear motion will have a greater effect on the wake than the pitching of the rotor plane.

4.1 Cycle Harmonic Damping

Before setting out the derivation of the instantaneous damping coefficient it is first essential to set out the cycle total aerodynamic damping. The approach taken follows the derivation provided by Carta and Niebanck (1967) but for a rotor undergoing fore-aft motion rather than a pitching airfoil section. The authors would like to clearly acknowledge that the following derivation is a modification of existing concepts rather than a completely new derivation.

4.1.1 Linear Harmonic System in a Vacuum

To begin the derivation, let us start with the homogeneous equation of the wind turbine oscillating in linear fore-aft motion (denoted as x).

$$m\ddot{x}^* + c\dot{x}^*(t) + kx^*(t) = 0 \tag{1}$$

where we make an assumption of harmonic motion thus taking;

$$x^*(t) = x_0 e^{i\omega t} \tag{2}$$

which then gives.

$$\dot{x}^*(t) = i\omega x_0 e^{i\omega t} \quad (3)$$

$$\ddot{x}^*(t) = -\omega^2 x_0 e^{i\omega t} \quad (4)$$

Substituting these results into the equation of motion then gives;

$$5 \quad (-\omega^2 m - \overbrace{i\omega c}^c + k)x^*(t) = 0 \quad (5)$$

As highlighted by Carta and Niebanck (1967), the damping terms are contained within the imaginary term of the equation of motion. They continued that for similar linear systems, the damping should be contained within the imaginary terms of the differential equation.

4.1.2 Linear Harmonic System in Air

10 Now introducing the aerodynamic terms into the equation we arrive at the particular equation of

$$(-\omega^2 m - \overbrace{i\omega c}^c + k)x^*(t) = T_U^* \quad (6)$$

Still following the logical steps set down by Carta and Niebanck (1967), the unsteady thrust force can be written as

$$T_U^* = T_1 \ddot{x}^* + T_2^* \dot{x}^* + T_3^* x^* \quad (7)$$

Where,

$$15 \quad T_2, T_3 \in \mathbb{C} \quad (8)$$

but

$$T_1 \in \mathbb{R} \quad (9)$$

due to the rational that the T_1 represents the apparent mass terms of the system which are identified in terms of the instantaneous reaction forces of an impermeable disk in still air. Instantaneous reaction forces are in phase with the acceleration therefore real.

20 A similar rational was used in the SDOF torsional airfoil oscillator formulation by Carta and Niebanck (1967); Bisplinghoff (2013); Scanlan and Rosenbaum (1951), this time by directly comparing to Theodorsens theory (Theodorsen (1935)) in which a well known distinction is made between the real and imaginary parts of the Bessel function. By substituting in the Cartesian forms of the thrust force;

$$T_2 = T_{2R} + iT_{2I} \quad (10)$$

$$25 \quad T_3 = T_{3R} + iT_{3I} \quad (11)$$

we arrive at the following equation;

$$(m - T_1)\ddot{x}^* + (c - T_{2R} - iT_{2I})\dot{x}^* + (k - T_{3R} - iT_{3I})x^* = 0 \quad (12)$$

By assuming harmonic motion and collecting real and imaginary terms the equation is reduced to;

$$[(-\omega^2(m - T_1) + \omega T_{2I} + k - T_{3R}) + i(\omega(c - T_{2R}) - T_{3I})]x^* = 0 \quad (13)$$

- 5 By eliminating the mechanical damping terms, that is the terms present in a vacuum, the aerodynamic damping can be shown as;

$$\xi = -\omega T_{2R} - T_{3I} \quad (14)$$

This result will form a key step in the next decomposition.

4.1.3 Work done by a rotor in fore-aft motion

- 10 Let us now take a different decomposition of the thrust force into its constituent steady and unsteady parts.⁴

$$T_{TOTAL} = T_{MEAN} + T_{UR} \cos \omega t + T_{UI} \sin \omega t \quad (15)$$

Two options exist for the normalization of the thrust force, that is the freestream velocity, or with the inflow velocity thus accounting for the rotor movement. The former assumption simply implies that the unsteady coefficient will contain the freestream effects, for the expected velocity ratios expected for wind turbine pitching movement and freestream velocities.

- 15 This may cause some peculiarities in the appearance of the data similar that the lift coefficient overshoots seen by Muller-Vahl (2015) and Strangfeld (2015) in unsteady airfoil wind tunnel measurements. Nonetheless, the freestream velocity is taken as convention meaning that the unsteady features will be wrapped up into the unsteady thrust coefficient.

This gives the coefficient form;

$$C_{TOTAL} = C_{TMEAN} + C_{TUR} \cos \omega t + C_{TUI} \sin \omega t \quad (16)$$

- 20 The work performed over one cycle of rotor fore and aft motion can be given as;

$$W_T = \oint T_{TOTAL} dx \quad (17)$$

or in coefficient form,

$$C_{WT} = \oint C_{TOTAL} dx \quad (18)$$

Here the differential operator can be switched;

- 25 $dx = x_0 \sin \omega t d\omega t$ (19)

⁴ $T_{Unsteady}$ is hereafter abbreviated to T_U

and the integral range can be set from $0 < \omega t < -2\pi$ to capture a single cycle finally giving.

$$C_{WT} = - \int_0^{2\pi} [C_{MEAN} + C_{TUR} \cos \omega t + C_{TUI} \sin \omega t] x_0 \sin \omega t d\omega t \quad (20)$$

By assuming that the thrust force will be simple harmonic(or deviating minimally), evaluating the integral shows that the real unsteady term and the mean terms are both eliminated during the integration leaving

$$5 \quad C_{WT} = \pi x_0 C_{TUI} \quad (21)$$

This results can also be represented in the form.

$$C_{WT} = \pi x_0 C_{TUI} = x_0 C_{T0} \sin \phi \quad (22)$$

This result is the second of the building blocks required to extract the aerodynamic damping from the measurement or simulation data.

10 4.1.4 The third decomposition of the thrust force

Let us now inspect the unsteady thrust force terms further. If we assume the thrust to be a sinusoidal time dependent function, the unsteady thrust force can be given in Cartesian form;

$$T_U = T_{UR} + iT_{UI} \quad (23)$$

For a prescribed motion system the earlier homogeneous equation(equation 13) can be written as a particular equation thus
15 giving;

$$T_U = T_{UR} + iT_{UI} = [(-\omega^2(m - T_1) + \omega T_{2I} + K - T_{3R}) + i(\omega(C - T_{2R}) - T_{3I})]x \quad (24)$$

By equating real and complex terms we get;

$$T_{UI} = [(\omega(c - T_{2R}) - T_{3I})]x \quad (25)$$

This result provides the key to extracting the aerodynamic damping coefficient from the thrust data. From earlier we know that;
20

$$\xi = (-\omega T_{2R} - T_{3I}) \quad (26)$$

These two equations can be related through

$$\xi = - \frac{dT_{UI}}{dx} \quad (27)$$

Or written in the coefficient form

$$25 \quad \Xi = - \frac{dC_{TUI}}{dx} \quad (28)$$

Using the earlier result of;

$$C_{WT} = \pi x_0 C_{TUI} = x_0 C_{T0} \sin \phi \quad (29)$$

we can finally arrive at the conclusion that;

$$\Xi_{CYCLE} = \frac{d \frac{C_{WT}}{\pi x_0}}{dx} = -\frac{1}{\pi x_0^2} \oint C_{TOTAL} dx \quad (30)$$

- 5 This equation will form the basis of checking whether the instantaneous equation formulation is correct. In practice it also provides a useful debugging tool for the code implementation.

4.2 Instantaneous damping derivation

- In most formulations, certainly as shown above, only a cycle averaged value of aerodynamic damping is found. Bowles, Corke et al. (Bowles et al. (2014); Corke et al. (2014)) provided a breakthrough on this front by using the Hilbert transform to get an estimate of the magnitude and phase of a signal. If we inspect the following equation from the earlier whole cycle derivation, we may already see the general direction that such a method would follow.

$$C_{WT} = x_0 T_0 \sin \phi \quad (31)$$

The instantaneous damping derivation begins with yet another form of the basic equation of motion for prescribed fore aft motion of a wind turbine rotor. The prescribed motion leaves only the aerodynamic forces.

$$15 \quad m_t \ddot{x} + h^*(t) \dot{x}(t) + \kappa^* x(t) = T(t) \quad (32)$$

Into which we can insert the apparent mass or inertia of air Pitt and Peters (1983);⁵

$$m_{tair} = \frac{8}{3} \rho R^3 \quad (33)$$

$$(34)$$

and then the complex damping and stiffness terms can be described in polar form as;

$$20 \quad h^* = h_r + i h_I = \bar{h} e^{i\gamma_1} \quad (35)$$

$$\kappa^* = \kappa_r + i \kappa_I = \bar{\kappa} e^{i\gamma_2} \quad (36)$$

Thus we arrive at;

$$\frac{8}{3} \rho R^3 \ddot{x} + \bar{h} e^{i\gamma_1} \dot{x} + \bar{\kappa} e^{i\gamma_2} x = T \quad (37)$$

⁵The inertia is not used in this derivation and the apparent mass terms are actually later cancelled out. However it is important to note that the apparent mass analogy can be made for a rotor. If that were not true, then the first term would also be complex and this derivation would be invalidated

By introducing the natural frequency parameter ω_0 as;

$$\omega_0 = \sqrt{\frac{3\bar{\kappa}}{8\rho R^3}} \quad (38)$$

the equation reduces to;

$$\ddot{x} + 2h_0\omega_0 e^{i\gamma_1} \dot{x} + \omega_0^2 e^{i\gamma_2} x = \frac{3}{8\rho R^3} T \quad (39)$$

5 Now taking the Hilbert transform of both sides of the equation.

$$\ddot{\mathcal{X}} + 2h_0\omega_0 e^{i\gamma_1} \dot{\mathcal{X}} + \omega_0^2 e^{i\gamma_2} \mathcal{X} = \frac{3\mathcal{T}}{8\rho R^3} \quad (40)$$

where we replace the thrust and movement with their analytical signal counterparts,

$$\mathcal{X} = X + i\tilde{X} = x_{amp} e^{i\omega t} \quad (41)$$

$$\mathcal{T} = T_u + i\tilde{T}_u = A_t(t) e^{\phi(t)} \quad (42)$$

10 Equate the imaginary and real components,

$$-\omega^2 - 2h_0\omega \sin \gamma_1 + \omega_0^2 \cos \gamma_2 + i(2h_0\omega \cos \gamma_1 + \omega_0^2 \sin \gamma_2) = \frac{3}{8\rho R^3 x_{Amp}} (T_u + i\tilde{T}_u) e^{-i\omega t} \quad (43)$$

Again, the imaginary components correspond to the damping of the system.

$$2h_0\omega \cos \gamma_1 + \omega_0^2 \sin \gamma_2 \quad (44)$$

$$= \frac{3}{8\rho R^3 x_{Amp}} (\tilde{T}_u \cos \omega t - T_u \sin \omega t) \quad (45)$$

$$15 = \frac{3A_T(t)}{8\rho R^3 x_{Amp}} \sin \overbrace{(\phi(t) - \omega t)}^{\psi} \quad (46)$$

The left hand term of this equation correlates to the damping of the system normalized by the apparent mass of the air using a combination of the equations set down by Carta and Niebanck (1967), and the normalization highlighted by Bowles and Corke (Bowles et al. (2014); Corke et al. (2014)).

$$\xi = \frac{A_T(t)}{x_{Amp}} \sin \overbrace{(\phi(t) - \omega t)}^{\psi} \quad (47)$$

20 Finally we can normalize

$$\Xi(t) = \frac{\xi}{P_{dyn} A} = -\frac{A_{C_t}(t)}{x_{amp}} \sin \psi(t) \quad (48)$$

Where $\tilde{C}_t(t)$ is given by the Hilbert transformed thrust coefficient time series $C_t(t)$;

$$\tilde{C}_t(t) = \mathcal{H}[C_t] = -\frac{1}{\pi} \mathcal{P} \int_{-\infty}^{\infty} \frac{C_t(\tau)}{\tau - t} dt \quad (49)$$

thus giving the analytical signal magnitude;

$$A_{C_t} = \sqrt{C_t^2 + \tilde{C}_t^2} \quad (50)$$

and phase

$$\phi(t) = \arg(Y(t)) = \arg(C_t + \tilde{C}_t) \quad (51)$$

5 which gives us the phase difference between the lift and the fore-aft motion

$$\psi(t) = \phi(t) - \omega t \quad (52)$$

from the assumed motion,

$$X(t) = X_0 e^{i\omega t} \quad (53)$$

The time averaged damping then gives us the cycle damping:

$$10 \quad \Xi_{avg} = -\frac{1}{T} \int_0^T \Xi(t) dt \quad (54)$$

Like previously undertaken by Bowles and Corke (Bowles et al. (2014); Corke et al. (2014)) and Lennie et al. (2016) the cycle averaged damping formulation provided by Carta and Niebanck (1967) can be used as a comparison. For this derivation, the comparison will be compared against the formula derived earlier for the fore-aft motion of a rotor.

$$\Xi = \frac{d \frac{C_{WT}}{\pi X_0}}{dx} = -\frac{1}{\pi X_0^2} \oint C_{TOTAL} dx \quad (55)$$

15 Agreement between the two calculations provides a useful (although not completely “leak-proof”) verification that the analytical signal is well conditioned and that no implementation errors are present. Verifications undertaken in Lennie et al. (2016) for the original formulation showed less than < 1% variation between the methods, Bowles et al. (2014) also remarked on the good agreement.

20 On a practical side, Hilbert transforms are intended to analyse narrowband signals. It was previously established in Lennie et al. (2016), that numerical or experimental noise doesn’t cause problems for this formulation - therefore no signal filtering will be applied. Both original and phase averaged data was analysed, although only graphs of the phase averaged data are presented in the paper. In the original time series, stochastic variations due to turbulent inflow are present in cases with turbulence. Otherwise after a few cycles, the results converge to the phase mean.

5 Demonstration Case 1: Collective Blade Pitch

25 Having now presented the analysis methods, it is possible to use these methods to investigate an example case of floating platform wind turbine aeroelasticity. A case was selected that should demonstrate more complicated thrust damping behaviour, the case chosen is harmonic collective pitch in the presence of platform translation. Further potential test cases for future work would include harmonic platform movement in combination with;

- yawed inflow
 - inflow turbulence
 - gusts or sudden changes in direction
 - changes in airfoil performance through simulated active flow control
- 5 – non-synchronous pitch and platform movements

Harmonic collective pitch in conjunction with platform movement is a complicated test case, but it is still simple enough to give a good demonstration of this particular tool chain. The collective pitch motion was prescribed using the formula

$$\alpha = \alpha_0 \sin(\omega t + \phi_{pitch}) \quad (56)$$

The test case settings are given in Table 2.

Table 2. Demonstration Case 1 Simulation Settings

Rotor speed[rpm]	12.1
α_0 [°]	0.5
ϕ_{pitch} [-]	$0, 0.5\pi, \pi, 1.5\pi$
Inflow velocity [m/s]	11.4
$\omega_{pitch}, \omega_{platform}$ [rad/s]	0.5

10 The collective pitch cycle chosen is not a realistic control regime, it was chosen to give a clear demonstration of the method. The LLFVW simulation was run for 60 seconds with a single cycle chosen for analysis after the initial wake effects had died out. The instantaneous damping was calculated from the thrust data using the method already discussed. As a verification the two cycle average values were compared and had good agreement, the values are presented in table 1.

15 The cycle averaged aerodynamic damping values do in fact show that collective pitch does have an effect. While thrust forces tend to be positively damped (with this sign convention, that means good damping), we can see that the magnitude of the damping is altered. In figure 7, it is possible to follow the chain of logic that leads to these changes. In the thrust force sequences, it is possible to see that while there are some magnitude shifts, the more important feature is that the phase of the thrust force is shifted. This then manifests as changes to the aerodynamic damping.

20 A closer inspection reveals an interesting feature, that a 0.5π (green) phase shift of the pitching sequence leads to an almost constant thrust force. This may appear to be favourable to reduce the fatigue loads of the wind turbine. However, what has effectively happened is that there is no force in phase with the velocity of the movement, therefore there is no complex term, thus slightly negative aerodynamic damping. In this case, the system would be relying on the other sources of damping⁶ to reduce the amplitude of oscillation.

⁶i.e. structural or that provided by the floating platform

Table 3. Comparison of Cycle Damping Values

	Averaged Instantaneous Damping	Cycle Averaged Damping	Error
$\phi_{Pitch} = 0$	0.030	0.031	3.5%
$\phi_{Pitch} = \pi$	0.036	0.038	3.5%
$\phi_{Pitch} = 1.5\pi$	0.060	0.062	3.5%
$\phi_{Pitch} = 0.5\pi$	-0.001	-0.001	3.5%
Baseline	0.036	0.037	3.5%

In the opposite case with a pitch phase shift of 1.5π (yellow), the thrust force is more in phase with the velocity, thus opposing the movement of the rotor is enhanced. The cycle averaged damping reflects this with a stronger damping value. The instantaneous damping value starts to show some departure from a pure harmonic signal. This can be traced to the matching non-linearity in the thrust force which could arise from rotor wake interactions, it is these effects that are difficult to account for in a cycle averaged value. In the literature examples where a pitching airfoil was examined (Bowles et al. (2014); Corke et al. (2014); Lennie et al. (2016)), the non-linearities were very strong due to dynamic stall and caused strong spikes of aerodynamic damping. In simulations where sudden changes of operating conditions are present, the instantaneous damping method will highlight sudden drops in aerodynamic damping when they occur, even if they don't show up in the cycle averaged values.

6 Demonstration Case 2: Collective Blade Pitch Maneuver

The second demonstration case will attempt demonstrate one of the most useful aspects of the instantaneous damping approach. Again in this case, we will look at a collective blade pitch maneuver but this time the pitching will not be periodic. This highlights one of the advantages of the assumptions made in the derivation. The prescribed motion of the platform must be periodic, but the thrust force response has no restriction. This in turn means that we are free to try out any control maneuvers as long as the platform motion remains periodic.

The second demonstration case will consist of a simple 5.2° blade pitch maneuver at a rate of $4^\circ/s$. In total, 8 cases were simulated with the pitching beginning at different phase angles with respect to the harmonic translation of the platform. The platform translation had an amplitude of 2m with a frequency of 0.5 [rad/s]. These simulation values are summarized in table 4. The FVLLT simulation was run using the same inputs as listed earlier.

The results are presented in two sets with the negative blade pitch maneuver in figure 8 and the positive pitch maneuver in figure 9. For the negative blade pitch maneuvers, we can see a clear increase in aerodynamic damping when the blades are pitched as the rotor retreats. Pitching the blades as the platform is advancing causes a clear drop in the aerodynamic damping. For the positive blade pitch maneuvers, pitching as the rotor advances creates only a small increase of the aerodynamic damping compared to the retreating case. These kinds of results could help design a controller which restricts negative blade

Figure 7. Collective Pitch Damping Cycles

pitch rates as the rotor plane advances in order to maximise tower top stability. The same approach is also useful for cases with other variations like changes in rotor speed for start up or shut down.

Table 4. Demonstration Case 2 Simulation Settings

Rotor speed[rpm]	12.1
$\alpha_0[^\circ]$	0
$\alpha_{Maneuver}[^\circ]$	5.2, -5.2
$\omega_{pitch}[^\circ/s]$	4
$\phi_{pitch}[-]$	0, 0.5 π , π , 1.5 π
Inflow velocity [m/s]	11.4
$\omega_{platform}[\text{rad/s}]$	0.5
$X_0[\text{m}]$	4

7 Conclusions

The QBlade implementation of the Free Vortex Lifting Line method(LLFVW) proved to be a useful tool for analysing floating platform wind turbines. Comparisons against two independent test cases, using a variety of methods showed relatively good agreement in thrust forces, rotor power, blade forces and rotor plane induction. Along with the many verifications already undertaken in literature, it seems that the code will perform solidly even in these challenging cases. Further work is required to extend the same analysis with flexible blades, tower and eventually platform rather than prescribed motion; some of these topics are already under way.

A new formulation of the instantaneous aerodynamic thrust damping of a wind turbine rotor was described. The first demonstration case was used to verify that the cycle averaged damping values line up with well established methods. The case also showed how the system alternated between stable and unstable within a single cycle. The second demonstration case showed a more complicated pitch maneuver, the instantaneous damping method was useful in understanding the system but provided helpful information for designing control strategies. It would be useful in future work to generalize the method so that any mode shape could be analysed without having to undertake the extensive derivation described in this paper.

8 Code availability

The full implementation of QBlade is available for download <https://sourceforge.net/projects/qblade/>

9 Data availability

No additional data was generated that hasn't been included in this article.
