Abstract. ~~This paper presents a novel method of assessing the lift-to-drag ratio of a flexible wing kite by in situ aerodynamic measurement. Since wind tunnel testing is not feasible for large deformable kites the knowledge about their aerodynamics is insufficient. In a full-scale experiment it is possible to derive aerodynamic coefficients by measurement of relative flow angles and airspeed. Aerodynamic models~~ Wind tunnel testing of large deformable soft kites for wind energy conversion is expensive and in many cases practically not feasible. Computational simulation of the coupled fluid-structure interaction problem is scientifically challenging and of limited practical use for aerodynamic characterization. In this paper we present a novel experimental method for aerodynamic characterization of flexible membrane kites by in situ measurement of the relative flow, while performing complex flight maneuvers. We find that the measured aerodynamic coefficients agree well with the values that are currently used for flight simulation of kites are reasonably accurate and can be supported by the measured data.

~~The simulations are found to show unrealistic values for the soft kites. For flight operation in crosswind maneuvers where the traction force is kept constant, the angle of attack in some flight situations. We find that during nominal flight operation of the kite is inversely related to the relative flow velocity. For entire pumping cycles, the measurements show considerable variations of the aerodynamic coefficients, while the angle of attack varies of the kite varies in fact only in a narrow range. However, the measurements reveal significant variations of the aerodynamic coefficients during operation in an airborne wind energy system. These variations have their cause in a change of~~ This finding questions the commonly used representation of aerodynamic coefficients as sole functions of the angle of attack and stresses the importance of aeroelastic deformation for this type of wing. Considering the effect of the power setting (identical to the trim) solely as a rigid-body pitch rotation does not adequately describe the aero-structural behavior of the kite, steering commands and flight direction. Angle of attack and flight speed show adverse trends for a kite in crosswind flight that produces a constant lift force. Modeling a change in

~~We show that the aerodynamic coefficients vary as functions of the power setting (trim) as pitch motion only is insufficient for a precise aerodynamic model of a flexible wing kite~~ of the kite, the steering commands and flight direction.

1 Introduction

Airborne wind energy ~~aims at converting is the conversion of~~ wind energy into ~~power utilizing electrical or mechanical power by means of~~ flying devices. Some of the pursued concepts use tethered airplanes or gliders, while others use flexible membrane wings that are derived from surf kites or ~~para-foils~~ parafoils (Diehl et al., 2017). The present paper is focus-

ing on an airborne wind energy system (AWES) with ~~a flexible wing kite (van der Vlugt et al., 2013)~~ an inflatable membrane wing that is controlled by a suspended cable robot (van der Vlugt et al., 2013, 2019). Compared to ~~aircraft with rigid wings~~ rigid-wing aircraft, the aerodynamics of ~~flexible wing structures~~ tethered-membrane wings are not so well understood and kite development still relies heavily on subjective personal experience and trial and error ~~principle (Breukels, 2011)~~ processes (Breukels, 2011; Dunker, 2013). One reason for this is the ~~complex aerodynamics since the shape of the membrane structure is dependent on the force distribution~~ aeroelastic two-way coupling of wing deformation and air flow which can cause complex multi-scale phenomena. Another reason is a lack of ~~experimental data~~ accurate quantitative measurement data to support the design process. Soft kites such as leading edge inflatable (LEI) tube kites are highly flexible and have no rigid structure to mount sensors for ~~a precise aerodynamic measurement~~ precise quantification of the relative flow in the vicinity of the wing. This is why many experiments rely on ~~ground-based~~ ground-based force measurements and position tracking of the kite, ~~where the atmospheric wind velocity induces a big uncertainty (Hummel, 2017; Python, 2017)~~. The ~~In these experiments the environmental wind velocity introduced substantial uncertainties (Python, 2017; Hummel et al., 2018)~~.

With dimensions in the order of several meters ~~do not allow for big~~ large surf kites or ~~larger, utility scale versions to be tested in even larger kites for power generation exceed the size capacity of most~~ wind tunnels. ~~As the structural deformation is a main feature that determines the kite's flow field it is hardly possible to downscale a model for a wind tunnel test~~ Downscaling a physical model, as it is customary for ~~aircraft. A first full scale rigid-wing aircraft~~, would require a synchronous scaling of the aerodynamic and structural problems, which for a fabric membrane structure with seams, wrinkles, multiple functional layers and integrated reinforcements is practically very difficult, if not unfeasible. For example, scaled models of large gliding parachutes have been analyzed in the wind tunnel at NASA Ames Research Center (Geiger and Wailes, 1990), while a 25% model of the FASTWing parachute was tested in the European DNW-LLF wind tunnel (Willemssen et al., 2005). A first full-scale experiment to determine ~~a kite's geometry the shape of a kite~~ in controlled flow conditions was performed by de Wachter (2008). ~~They used several cameras to track the deformation~~ Using photogrammetry as well as laser light scanning the three-dimensional surface geometry of a small ~~surf kite in a wind tunnel~~ ram-air surf kite was measured in two larger wind tunnels. This geometry was used as boundary condition for computational fluid dynamic (CFD) analysis of the exterior flow. The results show ~~that deformations are highly important for a flexible wing kite but the~~ a substantial deformation of the membrane wing by the aerodynamic loading. Due to the difficulty of scaling, these results can not be transferred to larger kites for wind energy conversion that fly at higher speeds as they are used for power generation. Numerical.

In general, the numerical simulation of strongly coupled fluid-structure interaction (FSI) ~~tools are highly expensive for a three dimensional deform-able kite~~. LEI kites cannot be calculated with ~~problems is computationally expensive~~. If the flow is fully attached, standard panel methods ~~because the flow separates behind the thick leading edge with~~ viscous boundary layer models can be used for efficient calculation of the aerodynamic load distribution. While this approach works, for example, for ram-air wings at lower angle of attack, it is not feasible for LEI tube kites because of the inevitable flow separation region behind the leading edge tube. Breukels (2011) and ~~? modeled the chord-wise and span-wise deformations of a kite for their numerical analysis~~. de Wachter (2008) and Bungart (2009) performed CFD analysis on Bosch et al. (2014) develop multibody and finite element models of LEI tube kites and use an empirical correlation framework to describe the aerodynamic load distribution

on the membrane wing as function of shape parameters. Bungart (2009) performs CFD analysis using the deformed shape of the kite in de Wachter's wind tunnel experiment but those measured by de Wachter (2008), however, these results can not be used for extrapolated to different kites. Without including the deformations calculating the actual aerodynamics of a kite We conclude that without accounting for the aeroelasticity of the membrane wing an accurate aerodynamic characterization does not seem reliable. This is why at present experiments seem to be feasible. We further conclude that presently experiments seem to be the most viable option to determine the global aerodynamic characteristics of a kite.

In Table 1 we list experiments described in literature to determine the lift-to-drag ratio of kites.

Table 1. Methods Experimental methods for determining the lift-to-drag ratio for of soft kites. Size refers here to total wing surface area.

Hobbs (1990) conducted a performance study on different designs of one line kites used for anemometry. Stevenson (2003) was the first to assess the aerodynamics of a traction kite in a scientific way. He flew kites on a circular trajectory indoors and did outdoor towing tests with a kite. Table 1 gives an overview of experiments to determine the lift-to-drag ratios of kites. There is a big variety in the The relative flow velocity at the wing is denoted as v_a and the power setting u_p describes the symmetric actuation of the rear suspension lines of the kite. A high value of u_p means that the wing is powered, while a low value of u_p means that the wing is depowered (see Eq. 6). The variety of methods, test conditions and kites as well as in the results which generated results makes it difficult to derive a trend. Hobbs (1990) conducted a performance study of different single-line kite designs used for wind anemometry. A first quantitative aerodynamic assessment method for power kites was presented by Stevenson (2003), Stevenson et al. (2005) and Stevenson and Alexander (2006). The test procedure involves flying kites on a circular trajectory indoors as well as outdoor towing tests.

van der Vlugt (2009) determined a similar manual test procedure for determining the lift-to-drag ratio L/D for a hand-steered surf kite that flies of a surf kite was proposed by van der Vlugt (2009). The kite is flown in horizontal crosswind sweeps just above the ground in a crosswind maneuver. The method crucially relies on the precise knowledge of, measuring the achievable maximum crosswind flight speed $v_{k,\tau}$ of the kite at a downwind position together with the wind speed v_w . Assuming that the measured wind speed is identical with the wind speed at the position of the kite which can not be assured for an AWES flying at high altitudes. In their experiment they measured the atmospheric wind behind the kite. (Ruppert, 2012) used the same methodology but applied it on an AWES during operation. They had to estimate the wind at the kite's position which rendered the results less reliable but proved that the method works for bigger kites. kite, the lift-to-drag ratio can be calculated from (Schmehl et al., 2013)

$$v_{k,\tau} = \frac{L}{D} v_w. \quad (1)$$

- 10 The method can be generalized to characterize the aerodynamics of kites flying complex maneuvers by either measuring or estimating the unperturbed relative flow velocity v_a in the vicinity of the wing. Figure 1 shows a self-aligning Pitot tube setup mounted in the bridle line system between kite and its control unit. The placement of the Pitot tube in the bridle line system

Figure 1. Pitot tube during calibration in the wind tunnel (left) and suspended in the bridle line system of a remote-controlled 25 m² LEI V2 kite during a flight test (right).

- was chosen to avoid a perturbation of the relative flow by the wing and the control unit. However, Ruppert (2012) concluded that the quality of the measurement data of this setup was insufficient and thus estimated the wind speed at the kite from other available data. In lack of reliable velocity measurements, van der Vlugt et al. (2019) describe an approach to estimate the lift-to-drag ratio of the airborne system components from measured force and position data. Borobia et al. (2018) have mounted a Pitot tube directly on the center strut of a small surf kite to measure the relative flow speed. Together with the data of other onboard sensors, this has been used to feed an extended Kalman filter to get an optimal estimate of the aerodynamic force and torque generated by the kite as well as the relative flow velocity vector and other kite state variables.

20 Dadd et al. (2010) and Costa (2011) both built a towing test setup to create the kite's apparent flow by driving a vehicle. Operating on wind-calm days gives them good control over the used towing test setups to generate a variable relative flow at the wing. Operating at days with calm wind allows for measurements at well-defined relative flow conditions. Hummel (2017)-Hummel et al. (2018) developed a similar trailer-mounted towing test setup to measure the lift-to-drag ratio and aerodynamic coefficients of sports kites. Their setup also surf kites. The test procedure includes active depowering or, which, in general aerospace engineering terminology is denoted as a change in trim of the kite in the testing procedure. They use precise angular sensors on the ground but recommend the wing and measuring line angles at the test rig. For future experiments, Hummel recommends the use of an airborne flow sensor to avoid the uncertainty arising from atmospheric wind and tether sag. The companies Kitepower (), Kite Power Systems () and SkySails () are uncertainties caused by the wind environment and by the sagging of the tether. Behrel et al. (2018) describe a setup to measure the aerodynamic performance of kites for ship traction applications. Using a three-dimensional load cell to record the traction force vector and a wind profiler to determine the wind velocity at the kite, the technique is applied to determine the lift-to-drag ratio of kites during crosswind maneuvers.

The companies Kitepower B.V., a startup of Delft University of Technology, Kite Power Systems (KPS) and Skysails Power (Weston, 2018) are currently developing and testing AWES with soft kites. The sizes of their current products and prototypes that are operated on a single tether and controlled by a suspended cable robot. These prototypes have reached considerable sizes (see for example Fig. 2) and for this reason the use of measurement data acquired during flight operation is the only viable option for characterizing the aerodynamics of the complete airborne system. None of the other experimental setups presented

In May 2018 the AWES prototype of Kitepower B.V. employing a 40 m² kite exceeded a mechanical power of 100kW and 15kN tether force (Kitepower B.V.). (see Fig. ??) leave only the crosswind flight test as a viable option to measure the aerodynamic behavior of a complete system.

Figure 2. LEI V5.40 kite with 40 m² wing surface area controlled by a suspended cable robot. This prototype temporarily reached a tether force of 15 kN and a mechanical power of 100 kW during a test flight in May 2018 (Kitepower B.V., 2018).

15 in Table 1 is able to reproduce 1 allows to execute dynamic flight maneuvers, handle large and handle kites with a wingspan of

$b = 10\text{m}$, produce 10 m or larger, at flight speeds above 20ms^{-1} and withstand large pulling 20 m/s while withstanding tensile forces of several kilonewtons and more.

To avoid the uncertainty from an estimated wind speed for this testing method measuring the kN or more. It is the objective of the present study to develop an experimental method for aerodynamic characterization of large deformable membrane kites that are used for energy conversion. At the core of this method is a novel setup for the accurate measurement of the relative flow conditions at the flying kite is necessary. This is why in the experiment of this paper we installed a sensor setup for apparent flow magnitude and flow angles in the bridle system kite during energy-generation in pumping cycles. Since the setup is additional equipment for tests of a commercial prototype the mounting of the setup has to consume as little time as possible.

The paper is organized as follows. In Sect. 2 we describe the airborne components of the kite. Jann and Greiner-Perth (2017) developed a similar setup for a gliding parachute which measures power system, the measurement setup and the data acquisition procedure. In Sect. 3 we describe how the power setting is related to the angle of attack and flow velocity in the bridle lines between payload and canopy. By choosing such a setup that is independent from the ground station we have no limits in traction force and can measure power kites that produce much more lift force than usual sports kites of the wing and how the aerodynamic properties are derived from the measured data. In Sect. 4 the results are presented and discussed.

Position of the sensors on the AWES prototype: Tether force F_T and reel-out speed v_T are recorded at the ground station. GPS and IMU modules are mounted on the kite. The kite control unit steers the kite and measures current lengths of the steering and depower lines. Flow sensors for α_m , β_s and v_a are mounted in the power lines that connect to the leading edge of the kite.

2 System description and data acquisition

The kite power research group of Delft University of Technology uses an AWES prototype operated by Kitepower B.V. The experimental study is based on the AWES prototype developed and operated by the company Kitepower as a test platform. The system within the EU Horizon 2020 “Fast Track to Innovation” project REACH (European Commission, 2015). The prototype can be classified as a ground-generation pumping cycle AWES with a flexible wing kite. The power production is achieved in a cyclic flight pattern where the traction or power phase alternates with a retraction phase. During ground-generation AWES, operating a remote-controlled soft kite on a single tether. This general setup is illustrated schematically in Fig. 3 (right). The main system components are the ground station for converting the linear traction motion of the kite into electricity, the main tether and the C-shaped, bridled wing with the suspended kite control unit (KCU). In the following, we will denote the assembly of wing, bridle line system and KCU as “kite”. To generate power the kite is operated in cyclic flight patterns with alternating traction and retraction phases. During the traction phase the kite flies dynamic crosswind maneuvers to produce a high pulling force and reel out the tether so the generator produces power. Retraction phase means that the performs crosswind maneuvers, such as figure-of-eight or circular flight patterns, while the tether is reeled off a drum that is connected to a generator. In this phase the AWES generates electricity. For the subsequent retraction phase the crosswind maneuvers are stopped and the generator is operated as a motor to reel in tether where low tether force is desired. During reel-in the kite is in a rather static flight

Figure 3. Basic components of the kite power system (right), wing with suspended control unit, together denoted as kite (center), and measurement frame attached to the power lines (left). Sensor positions: tether force F_t and tether reel-out speed v_t are recorded at the ground station ①, GPS and IMU modules are mounted on the center strut of the kite ②, the kite control unit ③ actuates the wing for steering and changing its power state, measuring also the instantaneous lengths of steering and depower tapes, the relative flow sensors for inflow angles α_m, β_s and apparent wind speed v_a are mounted on a rigid frame ④ that is attached to the two power lines connecting to the inflatable leading edge tube of the wing. The depicted velocity v_a^* is the component of the apparent wind velocity v_a projected into the drawing plane.

condition and is 'depowered'. This means the trim of the kite is changed to a low power setting u_p to produce only minimum lift the tether. The pumping cycle mechanism is described in detail in (van der Vlugt et al., 2013). Figure ?? (right) shows a sketch of the system. Its main components are the ground station for conversion of linear traction motion into electricity, the single main tether and This phase consumes some of the generated electricity. To maximize the net gain of energy per cycle the wing is depowered during retraction. Both steering lines are released symmetrically such that the entire wing pitches down, to a lower angle of attack, which significantly reduces the aerodynamic lift force.

- 5 Just below the KCU the main tether splits into two power lines of constant length that run along the sides of the KCU and support the inflatable leading edge tube and partially also the strut tubes of the wing. This is depicted schematically in Fig. 3 (center and left) and in more detail in Fig. 5 (left) without the measurement setup. A short line segment connects the KCU to the end point of the wing with the suspended kite control unit (KCU). From the KCU several bridle lines connect to the kite (see Fig. ??). Both the kite and the ground station are prototypes developed by the kitepower research group in 2010. The employed kite model 'V3' is a 25m^2 LEI-kite, the ground station was designed for a maximum of 20kW mechanical power. main tether, while steering and depower tapes connect the KCU to the steering lines and eventually, via a fan of bridle lines, to the wing tips and trailing edge. Details on this specific layout will be described in the following section. The KCU can actuate
- 10

the two steering lines either symmetrically, to power and depower the kite, or asymmetrically, to steer the kite. The actuation of the wing as part of the kite is illustrated in Fig. 4. The photographic footage from 23 August 2012 is documenting tests of

Figure 4. Almost fully powered LEI V3 kite (left), depowered kite (center) and deformation of the wing by extreme steering input in depowered state (right). Dots indicate the end of the depower tape.

a mast-based launch setup. While the left photo is taken during crosswind maneuvers during power generation, the two right photos are taken during a flight maneuver close to the launch mast.

5 The sensors on the ground station ①, the kite ② and the KCU ③ are needed provide data that is required for the autopilot ;the aerodynamic sensors are optional measurement equipment for our research project. The flow measurement setup is portrayed in Fig.?? (left), it consists of three sensor units:-

- A pivotable pitot tube that aligns with the flow direction (differential pressure, barometric pressure and temperature are captured to calculate total flow magnitude)-
- 10 - Two angular vanes that measure the horizontal and vertical apparent flow angle. Their orientation is recorded by a total magnetic encoder with a resolution of 0.35° -

of the kite power system (see Fig. 3). The experiments described in this paper have been performed with a LEI V3 kite with a wing surface area of 25 m^2 , a battery-powered KCU for 2-3 hours of continuous operation and a ground station with 20 kW nominal traction power. These components have been developed by the kite power research group of Delft University of Technology and reflect the technology status in 2012 (van der Vlugt et al., 2013; Schmehl, 2014; Schmehl et al., 2014; van der Vlugt et al.,

~
The mounting of the flow sensors is installed in the power line bridles. These are the bridle lines connecting the main tether to
Because the membrane wing is continuously deforming during operation it is not as straightforward as for a rigid-wing aircraft to define the orientation of the leading edge of the kite which transfer the main kite relative to the flow. One option is to use the inflated center strut as a reference component to mount the flow measurement equipment (van Reijen, 2018; Borobia et al., 2018)
20 Mounting the equipment directly on the suspended KCU is not considered to be an option because this relatively heavy

component is deflected substantially when flying sharp turns (Fechner and Schmehl, 2018) and can also exhibit transverse vibrations. Another option is to mount the measurement equipment on the two power lines. These lines transfer the major part of the kite's aerodynamic force $F_{a,k}$. The inflow angles α_m and β_s are measured towards the normal on the plane formed by these lines. The sensors are mounted about $h = 8.5\text{m}$ away aerodynamic force from the wing to the tether and for this reason are generally well-tensioned and span a plane that characterizes the orientation of the kite (wing and suspended KCU). Considering the deformation of the membrane wing by asymmetric and symmetric actuation as well as aeroelasticity, we consider this plane to be the most suitable reference geometry.

Figure 3 (left) illustrates how the three relative flow sensors ^④ are mounted on a rigid frame that is attached to the two power lines about 8.5 m below the wing. In Appendix A we use a simple lifting-line model of the wing to show that the assumption of free stream conditions at this distance from the kite to avoid flow perturbation of the kite and KCU similar to is justified. The Pitot tube can rotate freely around its pitch and yaw axis to align with the relative flow, measuring the barometric pressure, the differential pressure and the temperature from which the apparent wind velocity v_a can be calculated. The two flow vanes are used to determine the inflow angles α_m and β_s which are measured from the normal vector of the plane spanned by the setup described by (Jann and Greiner-Perth, 2017). We assume free stream conditions at the sensor position (see Appendix A).

The measured two power lines. The two angles are measured by total magnetic encoders with a resolution of 0.35° . The data is recorded at a frequency of $f = 20\text{ Hz}$ and 20 Hz , converted to a digital signal by a Pixhawk microcomputer. It is sent [®] microcomputer, transmitted to the KCU and via antenna and from there to the ground station to be logged simultaneously with the other acquired data. all other acquired sensor data. It is important to note that the relative flow sensors are add-on measurement equipment for the present study and are not essential for the operation of the kite power system. More information on the sensors and the measurement setup can be found in (Oehler, 2017) Oehler (2017).

The new setup addresses two shortcomings of the earlier attempts to determine the relative flow conditions at a kite, illustrated in Fig. 1. Firstly, a self-aligning Pitot tube alone can measure only the magnitude of the relative flow velocity but not its direction. The orientation of the wing relative to the flow is however important information for the aerodynamic characterization. Secondly, the tensile suspension of the Pitot tube in the bridle system of the kite was not sufficiently robust against perturbations which negatively affected the quality of the measurement results. Jann and Greiner-Perth (2017) describe a similar setup for gliding parachutes, mounted in the bridle lines between payload and wing, to measure the angle of attack and relative flow speed. By choosing a setup that is flying with the kite we are able to acquire the relative flow conditions in situ, during operation of the full-scale system, and are not constrained by the traction force limit of a particular ground testing rig. This allows us to characterize also the aerodynamics of power kites that produce much more lift force than usual surf kites.

3 Data processing

? describes an estimation problem where data is available before and after the time of interest as 'smoothing problem'. In order to get the best estimate for angles and velocity at a given time a moving average filter using data before and after the point

of interest is applied. The matlab function 'smooth' with a default value for σ of 0.3 is applied on the raw data of voltages and pressures. This operation returns a smooth, realistic signal but filters oscillations originating from changes in the sensor's supply voltage and avoids problems with single rotary encoders and the pressure sensor can have missing data points (Oehler, 2017). The measurement can still and can also fluctuate due to variations of the supply voltage. To address these issues we apply a moving-average filter, using the Matlab[®] function *smooth* with a span of 7 measurement points (0.3 s). This operation returns a smooth signal while still being able to capture systematic oscillations that occur at frequencies of up to 1.2 Hz. The measured data is not intended for control, consequently the interest in real-time optimal state estimation is low. 1.2 Hz (Oehler, 2017). In the following, we describe how the relative flow data is used together with the data of the other sensors to determine the aerodynamic properties of the kite.

3.1 Coordinate systems for the airborne system

The tether coordinate system (index t) has its origin in

3.1 Geometry and reference frames

The geometry of the wing and the layout of the tensile support system, comprising bridle lines, steering and depower lines, as well as steering and depower tapes are illustrated in Fig. 5. The two pulleys are attached to the two branches of the rear bridle line systems and allow the steering lines to slip freely to adjust the line geometry to the actuation state. The instantaneous length of the depower tape is denoted as l_d . Both renderings show a depowered kite, as illustrated by the photo in Fig. 4 (center), using the design shape (CAD geometry) of the wing and thus not accounting for additional deformation.

As shown in Fig. 5 (right), we define two different reference frames to describe the orientation of the tether and the kite. The tether reference frame (x_t, y_t, z_t) is attached to the kite end of the tether with its origin at the bridle point, thus where the main tether splits up into the bridles (Stevenson, 2003) and uses the orientations of the last tether segment as z_t -axis. This is derived from the coordinate system B where the tether splits into the two power lines. The z_t -axis is tangential to the tether, while the x_t -axis is located in the plane spanned by the z_t -axis and the normal vector of the plane spanned by the two tensioned power lines. This definition is identical to the "kite reference frame" used by Fechner et al. (2015) as a basis for a point mass kite used in Fechner et al. (2015). The x_t -axis lies in the plane formed by the kite's symmetry plane and the last tether segment and is perpendicular to z_t , thereby pointing forward in flight direction (see Fig. ??) model. The measurement reference frame (x_m, y_m, z_m) is attached to the rigid frame on which the relative flow sensors are mounted. As depicted in Fig.

In order to define the measured quantities precisely which is vital to use the data from the angular vanes the structure of the flow measurement assembly is used as main reference frame. The z-axis (left), the z_m -axis is aligned with the two upright members of the frame, while the y_m -axis is aligned with the two vertical bars of the airborne wind energy system on-board measurement equipment (AWESOME), y-axis is parallel to AWESOME's horizontal bar (see Fig. ??). X-axis points forward in flight direction and is normal to both the plane formed by the V-shaped front bridle lines and AWESOME's main structure. The power line bridles are assumed to be straight lines with negligible inertia as suggested in Boshch et al. (2013), the x-axis is thus always aligned with the kite's heading.

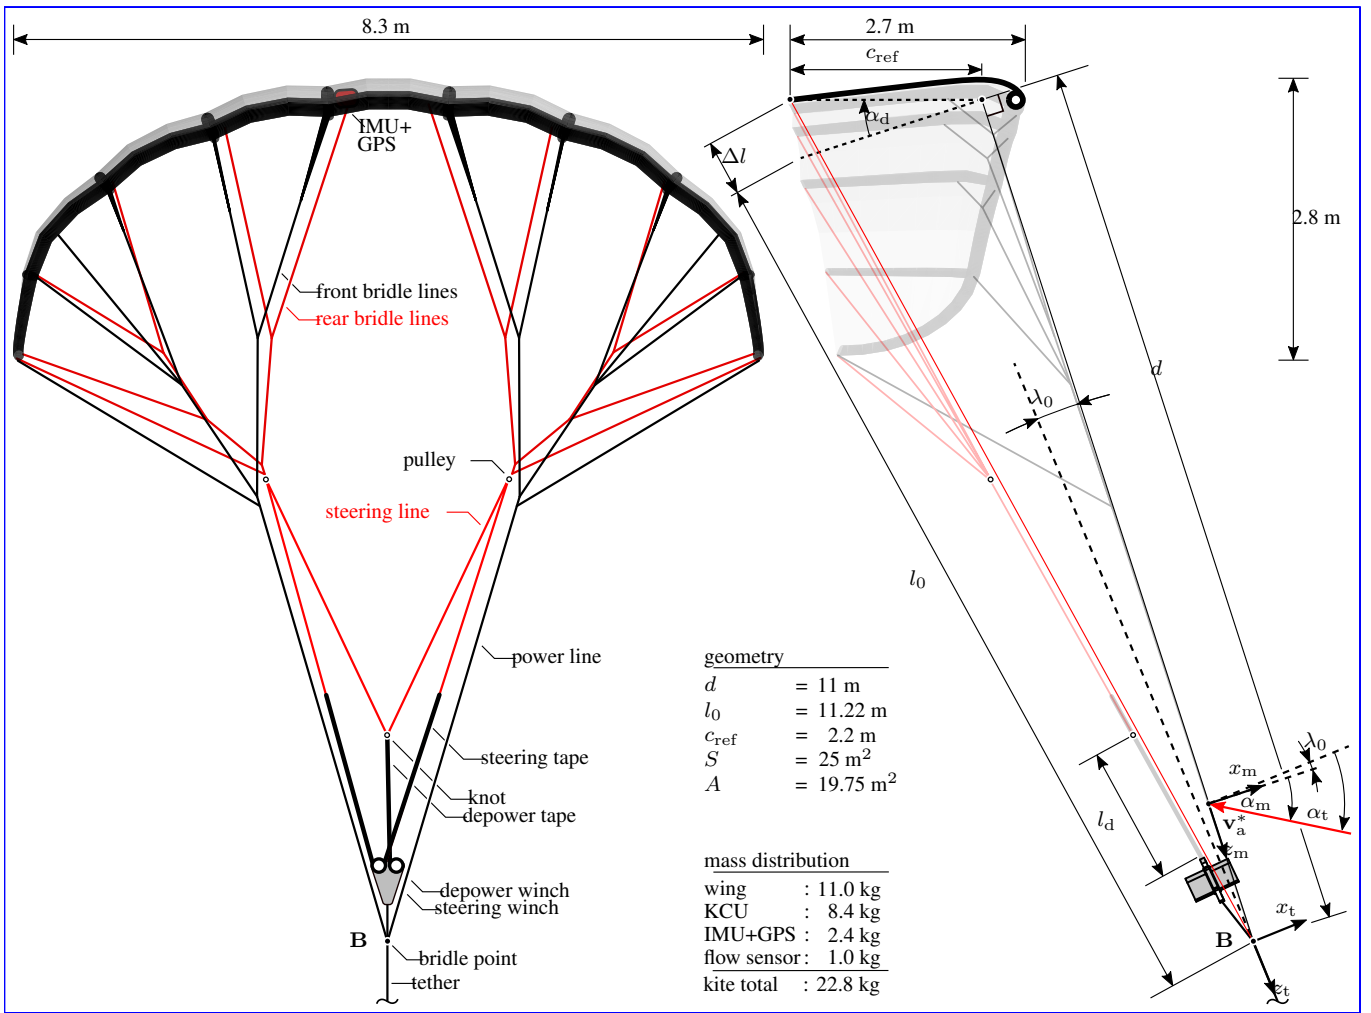

Figure 5. Front view (left) and side view (right) of the LEI V3 kite with reference frames, geometric parameters, mass distribution and definition of the reference chord c_{ref} . The total wing surface area is denoted as S , while the projected value is denoted as A . The mass of the bridle lines is part of the wing mass. The side view distinguishes between the physical (real) kite and bridle line system, displayed in the background, and the overlaid simplified geometric depower model. The explicit dimensions describe the unloaded design shape of the wing.

Reference frames to describe kite and sensor orientation towards the last tether segment. Both measured angles β_s and α_m are directly obtained in this coordinate system. As any yawing rotation of the kite results in the same yawing movement of the power lines and AWESOME, the obtained β_s can be directly referred to as transverse member. Because the measurement frame is attached to the two tensioned power lines the x_m -axis defines the heading of the kite. The rotation of the x_t -axis into the x_m -axis is described by the angle λ_0 , which is not constant and can not be controlled actively. The angle depends on the aerodynamic load distribution acting on the wing, the kite design and the bridle layout. The inflow angles β_s and α_m are determined in the measurement reference frame. Because the z_m -axis can be regarded as the yaw axis of the kite, the inflow

angle β_s is equivalent to the side slip angle. Similarly, the y_m -axis can be regarded as the pitch axis of the kite. To transform the measured angle α_m and the inflow angle α_m is a measure for its pitch orientation with respect to the relative flow.

To transform α_m into a meaningful angle of attack for the kite we need to of the wing we define a reference chord. Due to wing twist there isn't one chord orientation c_{ref} which describes the pitch orientation of the wing within the kite system as a function of the symmetric actuation of the steering lines. This two-dimensional, simplified geometric depower model is illustrated in Fig. 5 (right). For the fully powered kite, the reference chord is defined to be perpendicular to the plane spanned by the power lines. Depowering the kite is modeled as a pitching of the reference chord around the front suspension point, while the real wing additionally deforms by spanwise twisting and bending. The specific bridle layout of the LEI V3 kite shifts the front suspension point about 0.5 m backwards from the leading edge. The rotation is described by the depower angle α_d and by definition the fully powered state is given by $\alpha_d = 0$. A reference chord that is perpendicular to the power line plane is a reasonable approximation of the fully powered wing which is designed for optimal transfer of the aerodynamic load from the membrane wing to the bridle line system. These structural requirements are generally met best if the front bridle lines, which transmit most of the forces, connect perpendicularly to the wing. It is in principle straightforward to account for a constant offset angle α_0 (Fechner et al., 2015), however, for the investigated kite design this offset angle is rather small. For this reason we set $\alpha_0 = 0$.

The geometrical dimensions are extracted from the CAD geometry of the kite. The distance of the front suspension point from the bridle point is $d = 11.0$ m. For the fully powered kite, the distance of to the rear suspension point from the bridle point is $l_0 = 11.22$ m. The length of the reference chord can be determined as $c_{ref} = 2.2$ m. The kite is depowered by extending the rear suspension of the wing by Δl . In the following section, we relate this length extension to the deployed length l_d of the depower tape and the relative power setting u_p . The angle of attack of the relative flow with respect to the reference chord is calculated from the measured inflow angle and the depower angle as for a two dimensional profile. In traction mode with a relative power setting of $u_p = 1$ and depower angle $\alpha_d = 0^\circ$ we define the reference chord of the kite perpendicular to the power line bridles (see Fig.??). In this case the definition leads to α_m being equal to the angle of attack α .

$$\alpha = \alpha_m - \alpha_d, \quad (2)$$

while the angle of attack of the relative flow with respect to the tether reference frame is calculated as

$$\alpha_t = \alpha_m + \lambda_0. \quad (3)$$

The usual convention of using a soft kite's center chord as a reference seems hardly useful as its orientation towards the measured flow variables is unknown. The orientation of the center chord in flight varies due to the three dimensional deformation of the wing when it is loaded and it is doubtful whether it is representative for the chord orientation over the whole kite's span.

Figure 6 illustrates how the azimuth angle ϕ , the elevation angle β and the radial distance r are used to specify the position of the bridle point **B** relative to the ground attachment point **O**.

Ground experiments with the unloaded kite show that the center chord's orientation and the length of the steering lines are not related for the given bridle layout. The steering lines are connected to the tips of the kite and therefore cause a shape

For an unloaded kite on the ground, changing the power setting does not change center chord orientation systematically. The tips are

closer to each other for a higher power setting (bottom)

Figure 6. Ground reference frame (x_w, y_w, z_w) , tether reference frame (x_t, y_t, z_t) , heading angle ψ and spherical coordinates (β, ϕ, r) . Only in case of a straight tether, the z_t -axis is pointing in radial direction to the ground attachment point O.

deflection of the kite rather than a change in the orientation of the center chord. Even by varying the length of the steering lines by $\Delta l = 2.5\text{m}$ there is no significant variation in The heading angle ψ specifies the orientation of the orientation of the center chord but a deflection of the tips. Shortening the steering lines leads to a smaller distance from one tip to the other as it can be seen in Fig. ???. Only for a flying kite that produces lift distributed over its whole canopy we assume a relation between the power setting u_p and the effective aerodynamic orientation of kite in the wing. The uncertainty involved in the orientation of the kite's center chord is the main reason not to use the wing itself as a reference system.

3.2 Kinematic of 'depowering' the kite

- 10 For retraction phase when a low lift coefficient C_L and low lift-to-drag ratio L/D is desired, the power setting is reduced and the steering lines extended by Δl . The orientation of the effective chord is changed by α_d (see Fig. ??), and the angle of attack can be calculated with-

$$\alpha = \alpha_m - \alpha_d.$$

- 15 α_d as the depower angle was already introduced in Fechner et al. (2015). It is positive if the kite is being depowered for retraction and zero for the powered kite ($u_p = 1$) during traction phase. Instead of a linear correlation between the power setting u_p local tangential plane τ . The angle is measured between the local upward direction (dotted line) and the projection of the x_t -axis onto the tangential plane. Similarly, the course angle χ (not displayed) specifies the direction of the tangential kite velocity $\mathbf{v}_{k,\tau}$ in the local tangential plane. Combining Eqs. (2) and α_d as in Fechner et al. (2015) we derive the relation

with the help of the actual bridle geometry. By projecting the kite geometry of the 25 m² V3-kite into a two-dimensional substituted mechanical system as in Fig. ?? we can use the law of cosines to calculate α_d .

- 5 (3) to eliminate the measured inflow angle α_m we can differentiate three distinct contributions to the angle of attack

$$\cos(90^\circ + \alpha_d) = \frac{b^2 + c_{eff}^2 - (a + \Delta l)^2}{2dc_{eff}} \alpha_t - \lambda_0 - \alpha_d. \quad (4)$$

The distance from bridle point to leading edge The contribution of the tether angle of attack α_t is due to the flight motion of the kite is $d = 11\text{m}$, for the powered kite the distance from bridle point to trailing edge is $a = 11.22\text{m}$. c_{eff} is the distance between connection of the power line bridles to the leading edge tube and the connection of the steering lines to the back part of the kite. As these connections are located inwards from the leading edge and trailing edge the value of $c_{eff} = 2.2\text{m}$ is smaller than the kite's center chord of $c = 2.7\text{m}$ (see also Fig. ??), represented by the bridle point B, through the wind environment. The contribution of the line angle λ_0 is due to the pitch of the entire kite, represented by the plane spanned by the power lines, with respect to the tether. The contribution of the depower angle α_d is due to the pitch of the wing with respect to the plane spanned by the power lines. Δl is the effective change in the length of the steering lines. It is calculated with-

15 3.2 Kinematics of depowering

Instead of assuming a linear correlation between the relative power setting u_p and the depower angle α_d , as proposed by Fechner et al. (2015), we use the geometric depower model illustrated in Fig. 5 (right) to calculate an analytic equation for the depower angle α_d by applying the law of cosines

$$\cos(90^\circ + \alpha_d) = \frac{d^2 + c_{ref}^2 - (l_0 + \Delta l)^2}{2dc_{ref}}. \quad (5)$$

- 20 Considering the specific layout of the actuation system depicted in Fig. 5 (left), the extension of the rear suspension of the reference chord is approximated as

$$\Delta l = \frac{(1 - u_p)l}{2} l_d = \frac{1 - u_p}{2} l_{d,max}, \quad (6)$$

where l is the where l_d is the deployed length of the depower tape used in the flight experiment of $l = 1.7\text{m}$. As with the maximum value $l_{d,max} = 1.7\text{m}$. Because we employ a pulley system is implemented to decrease the control force needed only half required forces in the actuation system, only half of the length of the depower tape is translated into lengthening or shortening the steering lines. The maximum depower angle used in the observed data set is $\alpha_d = 24^\circ$ for a power setting of $u_p = 0$ rear suspension of the reference chord. Equation (6) shows that a full depowering of the wing with $u_p = 0$ leads to a maximum extension $\Delta l_{max} = 1/2 l_{d,max}$, from which a maximum depower angle of $\alpha_{d,max} = 24^\circ$ can be calculated on the basis of Eq. (5).

- 30 In this work the kite is treated as lifting surface with a fixed geometry that can be pitched by the forces acting on it and by lengthening and shortening the steering lines ?? A pitching rotation of the kite Aside of a general increase of the aerodynamic

load, an increasing angle of attack leads also to a gradual backwards shift of the load distribution, towards the rear of the wing. To balance this load shift, the entire kite has to pitch down, around the bridle point ~~has no effect on the orientation of reference chord towards the~~, which increases the angle λ_0 . This aerodynamic characteristic of LEI tube kites has been observed experimentally by Hummel (2017) and van Reijen (2018). Because the chordwise location of the center of pressure controls how the total aerodynamic load is distributed on the front and rear bridle line systems, measuring the line forces is a way to quantify the load shift. To describe how much of the total load is transferred through the front bridle lines ~~Only if the power setting is changed, thus the length of~~, we define the force ratios $F_{t,f}/F_{t,r}$ and $F_{t,f}/(F_{t,f} + F_{t,r})$, where $F_{t,f}$ and $F_{t,r}$ are the magnitudes of the resultant forces transferred through the front and rear bridle line systems, respectively (see also Fig. 11). The force ratios measured for a LEI Hydra V5 kite are illustrated in Fig. 7, indicating that the aerodynamic load gradually

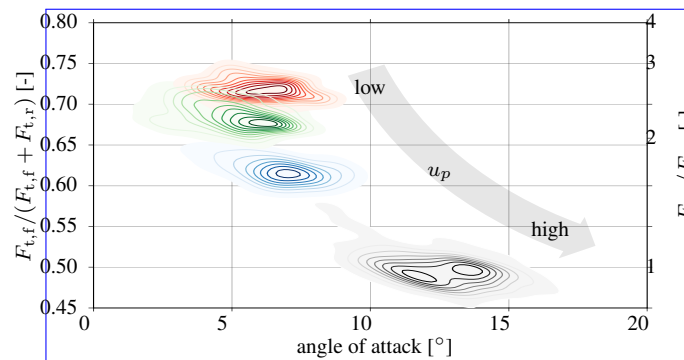

Figure 7. Distribution of tensile forces in the bridle line system, from low to high power setting (red, green, blue, black) measured for a commercially available LEI Hydra V5 kite with 14 m^2 wing surface area, by Genetrix Kiteboarding (adapted from van Reijen, 2018).

shifts towards the rear bridle lines for increasing power setting u_p . At the highest power setting the loads transferred through the front and rear bridle line systems are about equal. Since we did not measure the bridle line forces of the LEI V3 kite we assume a constant position of the center of pressure, derived as an average of several different types of kites by Hummel (2017). Measuring the bridle line force ratio for the LEI V3 kite in flight would help increasing the accuracy of this study but would require additional instrumentation and is recommended for future tests.

However, it is not only the shifting center of pressure that affects the orientation of the kite with respect to the tether. Another important factor is the ~~steering lines is collectively changed the kite's chord orientation~~ gravitational and inertial force of the KCU, which contributes almost 40% of the kite system mass and is suspended below at considerable distance from the wing (see Fig. 5). When the kite is flying upwards, the gravitational force is pulling the suspended KCU down, increasing λ_0 , while when it is flying downwards, the effect is inverted and λ_0 is decreased. When the kite is flying sideways, the mass of the KCU affects the roll orientation of the kite with respect to the ~~power lines and the apparent flow reference frame changes~~ tether. In general, the gravitational effect of the KCU increases towards lower elevation angles and lower tension in the tether.

The kinematic relations are obviously a simplified two dimensional approximation. The complex three dimensional deformation of the kite can with the current knowledge not be represented in an analytic model.

3.3 Determining lift-to-drag-ratio with tether angle α_t

In Fig. ?? the angle competing effects of kite aerodynamics and KCU mass are illustrated in Fig. 8 for two extreme load cases. The partially depowered kite on the left is flying statically and is thus only lightly loaded. For this reason, the rear bridle

Figure 8. Sideview of kite, partially depowered during landing maneuver (left) and fully powered during crosswind flight maneuver (right). The photo on the right was taken during a flight test in which the KCU was replaced by a ring that collected the joined power lines and the two steering lines and redirect them as a triplet of parallel lines to the pilot on the ground. The position of this ring is hinted by an overlaid transparent image of the KCU.

- 5 lines are sagging and the wing membrane is not taut. From the photo we can measure a depower angle $\alpha_d = 5.6^\circ$ and a line angle $\lambda_0 = 14.7^\circ$. The relatively large line angle indicates that the gravitational effect of the KCU mass by far outweighs the aerodynamic effect. On the other hand, the fully powered kite on the right is flying fast crosswind maneuvers and is thus heavily loaded. As a result, the wing membrane and bridle lines are taut. In this particular test, the wing is operated without KCU and λ_0 is introduced. The variable describes the orientation of the kite's front bridle lines towards the last tether segment which is
- 10 depends thus solely on the aerodynamic load distribution on the wing. From the photo we can measure a line angle $\lambda_0 = 5.1^\circ$ and can further recognize that the same angle that rotates the apparent flow reference system into the tether coordinate system. λ_0 cannot be actively controlled, its value is a result of the forces acting on the kite. In order to relate the direction of the apparent flow to the last tether segment we use

$$\alpha_t = \alpha_m + \lambda_0,$$

~~where all angles are visible~~ concept of a reference chord that is perpendicular to the front bridle lines is a good representation of the actual center chord of the wing.

5 In this work, the wing is idealized as lifting surface with fixed geometry. The proposed geometric depower model is a simplified two-dimensional approximation of the complex three-dimensional aeroelastic response of the bridled membrane wing. The photographic footage depicted in Fig. ??, ~~α_T is used to determine the kite's lift to drag ratio L/D .~~ 9 illustrates how the wing shape changes when transitioning from depowered to powered state. The GoPro® video camera with ultra-wide angle

Figure 9. Depowered kite (top) and powered kite (bottom) from a video camera mounted on the KCU and looking into the wing. The video sequence of the entire maneuver is available from Schmehl and Oehler (2018).

“fisheye” lens captures the entire wing and bridle line system, from which we can make several qualitative comparisons. It is obvious that the powering of the wing tensions the entire bridle line system such that the two pulleys (marked by circles) move forward, towards the leading edge. The increasing projected center chord indicates that the wing pitches into the projection plane. The slightly increasing projected span indicates that the entire wing straightens under the substantially increased aerodynamic loading when being powered. This effect is also described by van Reijen (2018, p. 61). Also the curvature (sweep) of the leading edge tube slightly decreases. It is clear that these effects can not be described by a geometric model without accounting for the fluid-structure interaction problem, including membrane wing, bridle line system and steering actuation.

15 ~~Estimation of the~~

3.3 Determining the Lift-to-drag ratio

A common method to estimate the lift-to-drag ratio of a kite is ~~usually achieved by flying the kite in its static equilibrium position and measuring the kite's to measure the~~ elevation angle β (Stevenson, 2003). ~~However this method inflicts of the tether with the horizontal during static flight~~ (Stevenson, 2003). A disadvantage of this method are the uncertainties arising from the

tether sag and the usually unknown wind conditions at the position of the kite. ~~As in Stevenson (2003) α_t is introduced as an angle accounting for all the forces acting~~ Stevenson (2003) introduces the tether angle of attack α_t to account for all forces acting on the kite system above the bridle point. ~~The tether inflow angle defined in Eq.3 is thus of high interest for describing~~, in our case, the KCU, the bridle line system and the wing. This angle, which is related to the measured inflow angle α_m by Eq. (3), can thus be used to characterize the aerodynamics of the kite. ~~But the value changes with the flight situation. To derive the purely aerodynamic entire kite.~~ However, the value of α_t depends also on the gravitational and inertial forces acting on the kite components. These vary with the specific flight situation such as flying upwards, downwards, sideways or turning maneuvers, as outlined in the previous section.

To understand how the aerodynamic characteristics of the kite are related to the kite design and measured properties we first neglect the effect of gravity. For steady flight, the resultant aerodynamic force \mathbf{F}_a is in equilibrium with the tether force \mathbf{F}_t . Because the flexible tether can only support a tensile force but no bending moment, the two forces are tangential to the tether at the bridle point, pointing in opposite directions. The aerodynamic force can be further decomposed into lift and drag components, \mathbf{L} and \mathbf{D} , respectively. By definition, the drag force is aligned with the apparent wind velocity vector \mathbf{v}_a and because \mathbf{F}_a is aligned with z_t , the lift-to-drag ratio L/D ~~we need to take into account the effect gravity has on the force equilibrium of the kite.~~ Figure ?? shows all forces acting on kite and KCU lumped into the bridle point. The lift-to-drag ratio can be calculated with-

$$\underline{L/D = \frac{L}{D} = \tan(\alpha_t - \Delta\alpha).}$$

is related to the tether angle of attack α_t by

$$\underline{\frac{L}{D} = \cot \alpha_t.} \tag{7}$$

Deriving aerodynamic lift-to-drag ratio L/D from tether angle α_t . All forces acting on the airborne system are condensed into the bridle point. Since the model integrates all forces above the bridle point, When flying on a curved path, as, for example, during figure-of-eight maneuvers, the centrifugal force perpendicular to the tether needs to be balanced by an additional lateral component of the aerodynamic force vector. How this side force $F_{a,s}$ in y_t -direction is generated depends on the specific type of wing and the aerodynamic coefficients L/D and C_L are alwas given for the entity of canopy, bridle lines and KCU. $\Delta\alpha$ accounts for the weight of the kite and KCU. $\Delta\alpha$ can be calculated by implemented steering mechanism. Classical rigid wing concepts with aerodynamic control surfaces (Ruiterkamp and Sieberling, 2013) and the Skysails ram air wing (Erhard and Strauch, 2013) roll the wing such that the lift vector tilts towards the center of turn. Most flexible membrane wing concepts, on the other hand, yaw and twist the wing, using the vertical surface of the wing tips to generate a side force and turning moment. This mechanism is depicted in Fig. 4 and described in more detail in Bosch et al. (2013, Sect. 17.3.1) and Fechner and Schmehl (2018, Sect. 15.2.2).

In a similar way, the effect of gravity needs to be balanced by an additional component of the aerodynamic force vector. This is formally expressed by the force equilibrium at the bridle point for steady flight

$$5 \quad \underline{\Delta\alpha} \underline{\mathbf{F}_a} + m\mathbf{g} + \mathbf{F}_t = \tan^{-1}\left(\frac{mg \cdot \cos(\beta) \cdot \cos(\chi)}{F_t + mg \cdot \sin(\beta)}\right), 0. \quad (8)$$

using the heading χ , the mass of the total airborne system of $m = 22.8\text{kg}$, the However, in difference to the centrifugal acceleration during turning maneuvers, the resultant gravitational force mg acts not only sideways but depending on the orientation of the kite in all three directions, x_t , y_t and z_t . To derive the required balancing components of \mathbf{F}_a , we express the resultant gravitational force of all kite components in the tether reference frame

$$10 \quad m\mathbf{g} = \begin{bmatrix} -\cos\beta \cos\psi \\ \cos\beta \sin\psi \\ \sin\beta \end{bmatrix} mg. \quad (9)$$

This representation is based on the assumption of a straight tether, such that the angle between the horizontal and the z_t -axis is identical to the elevation angle β and the tether force F_t . When flying horizontally with a heading angle of $\chi = \pm 90^\circ$ gravity influence is offset by a sideslip angle (Fechner and Schmechl, 2018). For heading angles indicating upward flight $\chi \in (-90^\circ; 90^\circ)$, we expect of the kite (see Fig. 6).

The force equilibrium given by Eq. (8) is illustrated in Fig. 10 for the special case of an upwards oriented kite ($\psi = 0^\circ$). The

Figure 10. Force equilibrium of a kite in steady-state flight, for the special case of the kite oriented upwards with $\psi = 0^\circ$, flying in the plane spanned by the wind velocity vector and the vertical, described by $\phi = 0^\circ$. The forces acting on the kite components are lumped to the bridle point. See (Schmechl et al., 2013, Fig. 2.11) for an illustration of the force equilibrium extended to the general case of kite flight in three dimensions.

15 vector diagram shows how the gravitational force is compensated by an upwards rotation of the aerodynamic force by an angle $\Delta\alpha$. For arbitrary orientation of the kite, the aerodynamic force components that are required to compensate the gravitational

force are given by the inverse of Eq. (9). Considering the compensation in the $x_t z_t$ -plane only, we can derive the following relation between tether force, gravitational force and the compensation angle $\Delta\alpha$

$$\tan(\Delta\alpha) = \frac{mg \cos \beta \cos \psi}{F_t + mg \sin \beta}, \quad (10)$$

which is illustrated by the shaded right triangle in Fig. 10 for the special case $\psi = 0^\circ$. Using the tether angle of attack α_t defined by Eq. (3), the lift-to-drag ratio can be determined from

$$\frac{L}{D} = \cot(\alpha_t - \Delta\alpha). \quad (11)$$

The gravitational force in y_t -direction is compensated by a steering force

$$F_{a,s} = -mg \cos \beta \sin \psi, \quad (12)$$

which, for the investigated type of kite, is generated by a sideslip angle β_s (Fechner and Schmehl, 2018). When flying figure-of-eight maneuvers, the angles β and ψ are continuously varying and the gravity compensation is accordingly alternating through x_t -, y_t - and z_t -directions. Neglecting this effect would have the consequence that the measured aerodynamic characteristics seemingly vary along the flight maneuver.

For orientations with upward component ($-90^\circ < \psi < 90^\circ$), we obtain positive values for $\Delta\alpha$, for the opposite case gravity has a component in the direction opposing the wing's drag which results in a negative value. For orientations with downward component, gravity opposes the aerodynamic drag of the wing resulting in negative values for $\Delta\alpha$. The elevation angle β is the kite's elevation angle which is obtained from of the kite is determined by the position of the kite with respect to the ground station. Sagging of the tether is neglected, as the tether being straight, sagged, long or short (see Fig. 6) and only in case of a straight tether identical to the inclination of the tether force (see Fig. 10). One of the key advantages of the described measurement method is that sagging of the tether does not directly affect the measurement of L/D which is one of the key advantages of this measurement method over angular measurements on the ground (Hummel, 2017). The absolute value of the tether force plays a role only in so far that it changes. We use the elevation angle β only to correct for the effect of gravity in Eq. (10). This correction is also affected by the ratio of weight gravitational force to tether force in Eq. 10.

In order to obtain α_t from the measurements, the angle between main tether and power lines. In contrast to this, sagging has a direct effect for methods that are based on ground-based measurements of the tether angle of attack, as proposed, for example, by Hummel (2017).

The tether angle of attack α_t can be calculated from Eq. (3), using the measured inflow angle α_m and the line angle λ_0 is needed (Eq. 3). It is calculated by solving the substituted mechanical system. The latter is determined numerically by solving for the quasi-steady force equilibrium of the simplified mechanical model illustrated in Fig. ?? for its kinematic equilibrium position. We thereby assume that the kite flies in a quasi-steady equilibrium (?Oehler and Schmehl (2017)). Inputs are the tether force F_t acting in direction of z_t at the bridle point, the drag of the KCU 11. In this framework, the individual components of the kite are idealized as point masses which are exposed to external forces (gravity, aerodynamic lift and drag, tether force

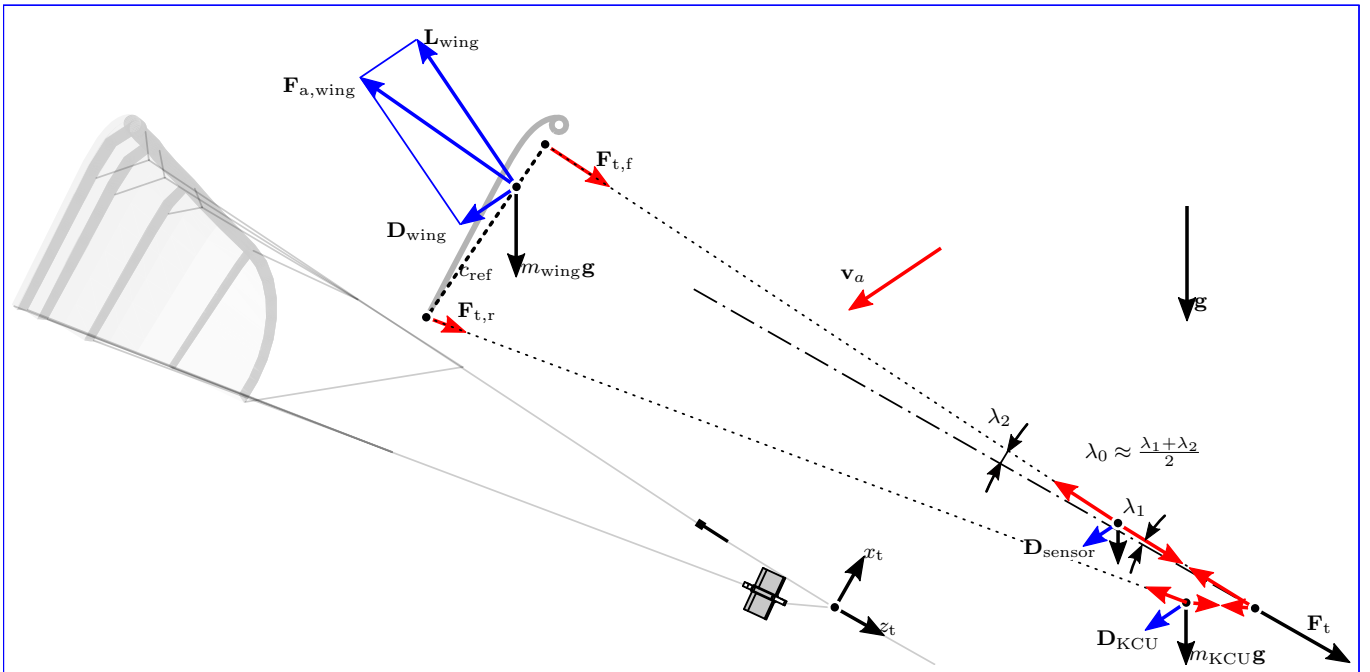

Figure 11. Fully powered kite (left) and simplified mechanical model of the kite system (right), including wing, measurement setup and KCU, showing external forces (black: gravitational forces and tether force at the bridle point, blue: aerodynamic forces) and internal forces (red: bridle line forces) to calculate the bridle line angles λ_1 and λ_2 . Depicted is the special case of an upwards oriented kite with apparent flow velocity and all model forces in the drawing plane. Force vectors are not to scale.

at the bridle point) and internal bridle line forces. The drag and the mass of the bridle line system are assigned to the wing. The total resultant aerodynamic force and the gravitational force acting on the kite components are thus decomposed as

$$\underline{F}_a = \underline{L}_{wing} + \underline{D}_{wing} + \underline{D}_{KCU} + \underline{D}_{sensor}, \quad (13)$$

$$\underline{m}g = (m_{wing} + m_{KCU} + m_{sensor})g. \quad (14)$$

In a first step, we calculate the resultant aerodynamic force $\underline{F}_{a,wing} = \underline{L}_{a,wing} + \underline{D}_{a,wing}$ that is required to balance the given tether force \underline{F}_t , and the individual mass contributions of KCU, kite and AWESOME. The model with a point mass for KCU and straight power and steering lines is similar to the one described in Bosch et al. (2013). All forces are acting at the same place as their related point masses (see Fig. ??). We assume both aerodynamic and gravitational forces acting on the kite components. Approximating the KCU and the measurement setup as blunt bodies with an aerodynamic drag coefficient of $C_D = 1.0$, we calculate a drag contribution of the KCU of about 10% of the wing drag and a contribution of the measurement setup of about 1%.

In a second step, we use a shooting method to iteratively adjust the bridle line angles until the two-dimensional model geometry for the known external forces and bridle line lengths is in quasi-steady equilibrium. For this we assume that a bridle

line force is always in line with the connection line of the two attachment points. We further assume that the center of pressure and the center of mass of the wing are both at 25% of the effective chord length reference chord (see Fig. 11). This is in line with Bosch's estimate for the center of mass and a force ratio of one third for a high power setting in Hummel (2017).

Both van Reijen (2018) and Hummel (2017) observe a shift in the center of pressure for different the mass distribution used by Bosch et al. (2013) and the average ratio of 3:1 for the forces in front and rear bridle lines measured by Hummel (2017) for different kites at various power settings. When the kite is powered up thus the steering lines shortened, the pressure point moves backwards. As we do not measure the difference in forces on the front bridle lines and steering lines we cannot account for this shift in center of pressure. The effect is different for every kite/bridle combination but a ratio of 3:1 for the forces in front and back bridles seems like a good average value. Starting from an initial guess for the line angle λ_1 , we calculate the angle λ_2 and the respective angles for the steering lines. Based on the resulting geometry, we then compute the distance between the front and rear bridle attachments on the chordline of the wing. If this distance is larger than c_{ref} , the value of λ_1 is reduced and the calculation repeated. The iteration loop is terminated when the target distance c_{ref} of the bridle attachment points is reached. The algorithm generally converges within 4 iterations, using a termination criterion of 0.01 m or 0.5%.

Substituted mechanical system of kite and KCU with external and internal forces for the calculation of the bridle lines' angles λ_1 and λ_2 . The tether sag does not need to be calculated and does not affect the calculation which is a big advantage over ground based measurements (e.g. Compared to ground based methods, for example, with angular sensors at the tether exit ground attachment point of the ground station). The influence of the aerodynamic sensors' weight tether, the sagging of the tether does not affect the measurement significantly. Also, the effect of gravity on the measurement setup was found to be negligible. The cause for this is that AWESOME is much smaller than This is because the measurement setup is a lightweight construction compared to the KCU and the tension in the power lines where it is installed is three times higher than the one in the steering lines, because the power lines are generally well tensioned. We have observed that the line angles λ_1 and λ_2 differed for only one or two tenth of a degree so in general differ only by 0.1° to 0.2° , such that the power lines are considered straight, we can practically be considered straight. We thus use the mean value of both λ_1 and λ_2 as line angle λ_0 . The KCU in contrast, on the other hand, has a considerable effect, especially during reel-in maneuvers when the force in the steering lines is small compared to the KCU mass rear suspension lines is of the order of the gravitational force of the KCU.

The calculated values vary between $\lambda_0 = 0 - 2^\circ$ $0^\circ < \lambda_0 < 2^\circ$ for flying downward. For upward flight and during reel-in we find values of $\lambda_0 = 3 - 7^\circ$ $3^\circ < \lambda_0 < 7^\circ$. For low tether tension and upward flight values of 10-12 degrees occur. This shows why a constant λ_0 cannot be assumed. $10^\circ < \lambda_0 < 12^\circ$ occur. These computed ranges agree well with photographic evidence, such as the snapshots shown in Fig. 8. The highest values occur when both tether tension and elevation angle are low which happens is the case during launch and landing.

When all lines are well tensioned and straight, the pitching of the kite around the bridle point does not affect the bridle geometry. However, the rear bridle lines are not always well tensioned, as can be seen clearly for the landing maneuver shown in Fig. 8 (left). When flying upwards during power production (see Fig 11), the effects of drag and gravity are both in a downward direction which can cause a measurable sag of the rear bridle lines. This effective shortening of the bridle lines increases the powering of the kite and can be modeled as a reduction of the depower angle α_d .

3.4 Deriving the lift coefficient C_L

With

$$L = \frac{1}{2} \rho C_L v_a^2 A$$

5 3.4 Determining the Lift coefficient

The lift coefficient C_L is a dimensionless number,

$$L = \frac{1}{2} \rho C_L v_a^2 A, \quad (15)$$

we can determine the kite's lift coefficient C_L . Density ρ and apparent flow velocity v_a characterizing the lift force as a function of the air density ρ , relative flow velocity v_a and projected wing surface area A . Density and relative flow velocity are measured directly, the projected kite surface area $A = 19.75 \text{ m}^2$ is known. Using the kite's while a constant value for the projected wing surface area is used (see the table included in Fig. 5). Using the lift-to-drag ratio L/D and the known influence of gravity we can compute the lift produced force generated by the kite L .

as

$$L = \sqrt{\frac{(\frac{L}{D})^2}{1 + (\frac{L}{D})^2}} F_{a,a} \sqrt{\frac{(\frac{L}{D})^2}{1 + (\frac{L}{D})^2}}. \quad (16)$$

15 The resultant aerodynamic force of We resolve Eq. (8) in horizontal and vertical directions to relate the force magnitudes as

$$F_a = \sqrt{(F_t \cos \beta)^2 + (F_t \sin \beta + mg)^2}, \quad (17)$$

again making use of the idealization that the airborne system F_a can be calculated from the tether force F_t , the elevation angle β and the airborne mass m (see Fig.??).

$$F_a = \sqrt{(F_t \cos \beta)^2 + (F_t \sin \beta + mg)^2}$$

20 is aligned with the radial direction from the ground attachment point. The special case of an upwards oriented kite with all forces in the drawing plane is illustrated in Fig. 10.

4 Results

—Picture of the in situ measurement of apparent flow magnitude and angles. The plot shows the raw values of apparent flow velocity v_a and inflow angles over time during an exemplary traction phase.

25 Data was collected- The data for this study was acquired during a one hour test flight of the prototype system described in Sect.?? on March described in Sects. 2 and 3.2 on 24 of March 2017 in Valkenburgairfield (the Netherlands). A at the former

naval airbase Valkenburg, close to Leiden, the Netherlands. A video camera mounted on AWESOME provided proof the measurement setup documented that all sensors were moving freely in the airflow and did not show exhibit any visible faulty behavior (see Fig.??). The plot shows the first 30s of a. This is illustrated in Fig. 12, with the diagram showing 27 seconds at the beginning of a representative traction phase. In all plots with time on the horizontal axis the launch of the kite corresponds to $t=0$ ¹ The first 180 seconds of the one hour test flight are available as video footage from Oehler and Schmehl (2018). The

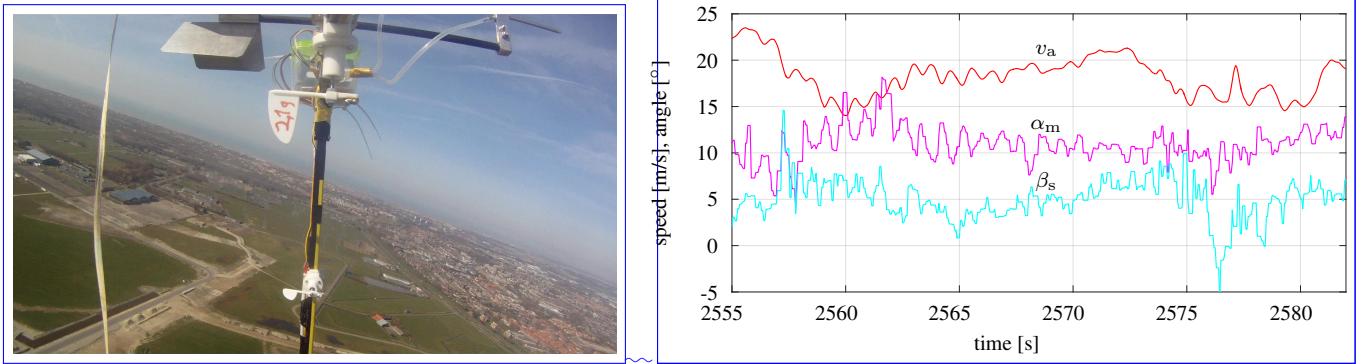

Figure 12. Video still of the relative measurement setup taken from the right power line (left), raw values of apparent flow velocity v_a and inflow angles α_m and β_s recorded over time at the beginning of a representative traction phase (right).

maximum speed occurs in the beginning of the plot apparent flow velocity occurs during the first two seconds of the depicted time window, when the transition from reel-in to traction phase is happening and the kite is flying downwards. Gravity helps to accelerate the kite to a high velocity. One first obvious result is that the measurement contradicts previous findings of Ruppert (2012) which indicate considerable variations in kite transitions from the retraction to the traction phase. Because the kite flies downwards during this maneuver, it is additionally accelerated by the effect of gravity, which leads to a temporary increase of the apparent flow velocity.

- Our measurements contradict the earlier study of Ruppert (2012), who reported considerable variations of the angle of attack of (up to 30 degrees during traction phase and also high angles of sideslip varying in $\beta \in [-20^\circ, 20^\circ]$. In the observed data set the α during the traction phase) and sideslip angle ($-20^\circ < \beta_s < 20^\circ$). In our study, the angle of attack showed only minor variations between 6 and 16 degrees during traction phase and from about -7 to 3 degrees for retraction phase is limited to a narrow range of $6^\circ < \alpha < 16^\circ$ during the traction phase. The measured angle of sideslip sideslip angle deviates from its mean by $\Delta\beta = 10^\circ$ for value by a maximum of $\Delta\beta_s = 10^\circ$ only during very sharp turns. Estimation of the flow angles without systematic flow measurement and estimation of the air speed, which is indicative for the high aerodynamic side force produced by a moderate side slip angle. We conclude that an accurate determination of the relative flow at the kite is not feasible without in situ measurements at the kite's position should be considered an insufficient way of determining a kite's flow field. The kite's speed lies around $v_a = 18 \text{ms}^{-1}$ for. Using only GPS and IMU data and ground based measurements, as proposed by Ruppert (2012), leads to a substantial degradation of the achievable accuracy. The apparent flow speed is around $v_a = 18$

¹In this study, time is counted from the launch of the kite, starting at $t = 0$.

m/s during the traction phase and ~~below $v_a < 15 \text{ms}^{-1}$ for retraction $v_a < 15$ m/s during the retraction phase.~~ In the analyzed experiment of March 24 data set, the mean value of the sideslip angle was not centered around a value of zero, which we would expect have expected for a symmetric kite. The reason for this was found in a non-symmetric bridle setup which caused This offset resulted from an asymmetric layout of the bridle lines, causing the kite to fly in a non-symmetric pattern during reel-out phase. To conduct a concise analysis of the influence of sideslip an asymmetric pattern during the traction phase. We recommend to investigate the effect of the sideslip angle on the kite 's aerodynamics a different experimental data set is needed. aerodynamics in a future study, using alternative data for a verified symmetric layout of the bridle line system.

5 A common technique to analyze measurement data from wind turbines or other rotating machinery is phase averaging. In contrast to Behrel et al. (2018) we did not use this technique because of the difficulty to determine a clear phase location of the data. Harvesting wind energy with tethered flying devices operated in pumping cycles has many more degrees of freedom than conventional wind turbines and even though the operation in a variable wind environment requires these to be actively controlled, the location of the lightweight devices along the flight path is tightly coupled to the evolution of the wind field along this path. For a wind turbine, with rotor blades that are mechanically linked and have a comparatively large rotational inertia, the determination of a phase location is comparatively straightforward. Instead of using rigorous phase averaging, we only differentiate between traction and retraction phases, subdividing the crosswind maneuvers further into flying upwards (against gravity) and flying downwards (with gravity). This can be regarded as a low resolution phase averaging, tailored to the specific physics of tethered flight in pumping cycles. However, the available data covered only five separate cycles, which is by far not sufficient for a meaningful statistical analysis.

4.1 Oscillation Reeling oscillations

Data-The flight data illustrated in Fig. ?? shows 12 exhibits strong fluctuations at a distinct frequency of $f_{GS} = 1.2 \text{Hz}$ in both v_a and α_m . This oscillation occurs several times during reel-in and reel-out for periods of several seconds. The values of tether force F_t and reel-out speed v_t , measured at the ground station 1.2 Hz in both v_a and α_m . These oscillations occur repeatedly for several seconds during the retraction and traction phases. Other independently measured variables also exhibit this behavior, for example, the tether force F_t , the tether reeling speed v_t , the pitch rate of the kite, as well as pitch rate, the forward and downward accelerations measured by the kite's IMU are other independent measurements showing the oscillation of the kite. In Oehler and Schmehl (2017) the strong damping of the kite system $\zeta_k = 0.63$ and its eigenfrequency for a pitch motion of $f_{k,traction} = 0.81 \text{Hz}$ during wing-mounted IMU. To identify the cause of these oscillations we considered two possible mechanisms in a previous study (Oehler and Schmehl, 2017): a first mode of radial oscillations of the kite that are commanded by the reeling control of the ground station and a second, flight dynamic mode. These tangential oscillations in forward/backward direction are kinematically coupled to pitch oscillations. Based on a simple model of a driven oscillator, we determined for the flight dynamic mode a relatively strong damping, with a coefficient ζ_k of 0.63, and eigenfrequencies f_k of 0.81 Hz for the traction phase and $f_{k,retraction} = 0.39 \text{Hz}$ during 0.39 Hz for the retraction phase. The fact that the kite oscillates during traction and retraction phase with $f_{GS} \neq f_k$ leads to the conclusion that we do not observe a Because these values differ from the frequency of the observed fluctuations we conclude that we are not observing a flight dynamic mode of

the kite system but a forced oscillation commanded by the ground station. Absence of this behavior whenever $v_T = 0$ supports the classification as forced oscillation that is governed by the control law of the ground station. This oscillation mode that the reeling controller of the ground station is the root cause of the oscillations. This is supported by the additional observation that the fluctuations cease when the reeling of the tether stops. It is clear that this behavior could be suppressed by adjusting an adjustment of the ground station controller, however, this is not part of this work the study.

To estimate the effect of this oscillation on the flow field of the kite, these forced oscillations with frequency $f_{GS} = 1.2$ Hz on the kite aerodynamics we determine the reduced frequency k is calculated. (Hassig, 1971)

$$k = \frac{f \cdot \pi \cdot c}{v_a} \frac{f \pi c}{v_a} \quad (18)$$

For the frequency of the oscillation $f_{GS} = 1.2$ Hz, Using a chord length of $c = 2.7$ m and an apparent flow speed of $v_a = 20 \text{ ms}^{-1}$ the reduced frequency is $k_{GS} = 0.5$ $v_a = 20$ m/s, we calculate a value of $k_{GS} = 0.5$. This means we have to expect highly unsteady aerodynamic behavior. This can lead to that the flow around the kite is unsteady, which in turn can cause a phase shift of the registered aerodynamic load with respect to the angle of attack. In order to minimize this effect, the data is smoothed. To mitigate the effect of a possible phase shift, we smoothen the data over an interval of $T = 2.5$ s $T = 2.5$ s which is equivalent to 3 periods of the oscillation. In case a phase shift between angle of attack and aerodynamic force occurs this should be compensated. This smoothing rule renders the three oscillation periods. In doing this we essentially regard the forced oscillations and resulting unsteady aerodynamics of the kite as a subscale process, which we filter out to retain the assumption of quasi-steady flight applicable for all flight phases except for turns where the kite is accelerated consistently.

For the figure-of-eight flight pattern we assume. To assess the effect of the turning maneuvers during crosswind flight on the aerodynamics of the kite we determine a characteristic frequency of $f_{turn} = 0.1$ Hz $f_{turn} = 0.1$ Hz which corresponds to the turning maneuvers where the kite performs a half turn in about five seconds. For these flight maneuvers we obtain a The corresponding reduced frequency of $k_{turn} = 0.042$ which is an indication that we can assume $k_{turn} = 0.042$ indicates that the aerodynamic time scale is more than an order of magnitude smaller than the turning time scale, which confirms the assumption of quasi-steady aerodynamics flight also from this perspective.

4.2 Lift-to-drag ratio

The lift-to-drag ratio L/D is a key parameter to characterize the aerodynamic performance of a wing. As described by Eq. (1), this parameter determines how fast a kite can theoretically fly in a given wind environment and by that also what tether force can be achieved for a given size of the wing (Loyd, 1980; Schmehl et al., 2013). In contrast to a conventional aircraft, the C-shaped flexible membrane wing is used as a single aerodynamic control surface with the double function of steering and generating a tether force that can be modulated over a wide range. This is of particular importance for the considered operation in pumping cycles because the achievable net energy per cycle crucially depends on the ability of the wing to alternate between a high lift-to-drag ratio during the traction phase and a low ratio during the retraction phase.

In Fig. 13 we investigate the influence of the angle of attack α of the wing and the power setting u_p of the kite. We choose two different ways to plot the The lift-to-drag ratio. First over the angle of attack defined in Eq.(2) which is customary for

Raw data of lift-to-drag ratio plotted over angle of attack (left) and power setting of the kite (right). No filtering is applied to the data.

Figure 13. Measured lift-to-drag ratio L/D of the kite plotted over the angle of attack α of the wing (left) and relative power setting u_p of the kite (right). No filtering or smoothing is applied to the data.

10 profiles and aircraft. Secondly we also plot L/D over the power setting u_p of the entire kite (all components from bridge point outwards) is derived on the basis of Eq. (11), using Eq. (3) to account for the measured flow angle α_m and the estimated line angle λ_0 , and Eq. (10) to account for the effect of gravity, expressed as compensation angle $\Delta\alpha$. No further filtering or smoothing is applied to the data. Although the effect of gravity on all kite components is taken into account as well as the aerodynamic drag on KCU and measurement setup, the data is still scattered considerably. In the following we will show that

15 this is for a considerable degree due to occasional dips in the tether tension, steering actuation and the associated sideslip angle.

Figure ?? shows the lift-to-drag ratio L/D plotted over the In Fig. 13 (left) we can distinguish a distinct region of lower angle of attack α (left) and over the power setting u_p (right). The data points are scattered, because there are many variables with an effect on the lift-to-drag ratio such as angle of attack, power setting, aerodynamic force, steering input and sideslip

20 angle, $-7^\circ < \alpha < 3^\circ$, indicating the retraction phases, and a distinct region of higher angle of attack, $7^\circ < \alpha < 15^\circ$, indicating the traction phases. In Fig. 13 (right) the retraction phases are indicated by power settings $u_p < 0.55$, while the traction phases are indicated by power settings $u_p \approx 1$. In Fig. ?? only the models from Sect. ?? are used but no further filtering is applied. It is apparent that there is a region where the kite flies at a low angle of attack in the range $\alpha \in [-7, 3]$ and one region with higher $\alpha \in [7, 15]$. Low angles of attack indicate the reel-in period, high angles of attack indicate the traction phase. On the right side

25 the power setting u_p allows a clear separation between reel-in phase with $u_p < 0.55$ and reel-out phase with $u_p \approx 1$. Values in between mark these regions are typical for the transition between both flight states. The retraction and traction phases. During the traction phases we measure an average lift-to-drag ratio lies around $L/D = 4$ for the traction phase and at a lower $L/D = 3$ during retraction which is what is desired to limit the traction force during reel-in. ratio of about $L/D = 4$, during the retraction phases we measure an average ratio of about $L/D = 3$, which is desired to reduce the tether force and thus also the energy consumption during retraction of the kite.

Table 2. Three filtering procedures applied to the measured lift-to-drag ratio.

<u>filter</u>	<u>description</u>	<u>reason</u>	<u>visible effect</u>
<u>height1</u>	<u>moving average</u> <u>over $T = 2.5$ s</u>	<u>forced oscillations with f_{GS};</u> <u>remove subscale dynamics.</u>	<u>reduces spread</u> <u>during retraction</u>
<u>2</u>	<u>$F_t > 400$ N</u>	<u>model limitation</u>	<u>eliminate outliers</u>
<u>3</u>	<u>exclude steering</u>	<u>strong deformation</u>	<u>eliminate outliers</u>

In the next step we filter the data as outlined in Table 2, reducing the spreading and removing outliers. The correlated effect of the angle of attack and the relative power setting on the lift-to-drag ratio is illustrated in Fig. 14, where we have also applied the moving average smoothing described in Sect. 4.1 (filter #1).

Lift-to-drag ratio with colors indicating the power setting u_p of the kite. Red stands for the highest power setting during traction phase $u_p = 1$, blue signifies

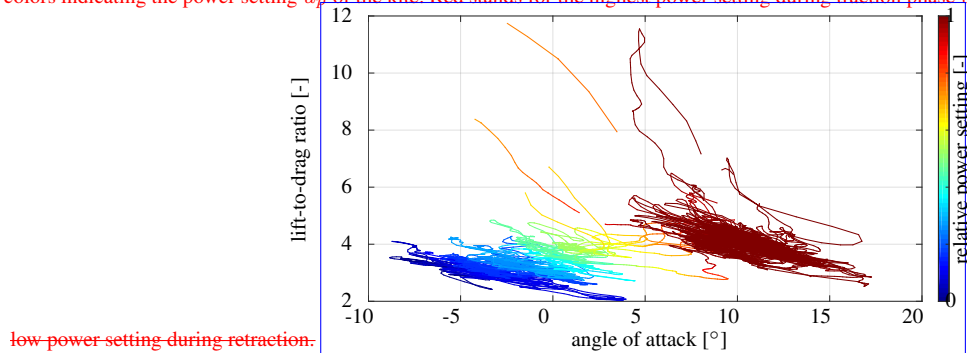

Figure 14. Measured lift-to-drag ratio L/D of the kite plotted over the angle of attack α and colored by the relative power setting u_p . The coloring ranges from blue, for lower values of u_p when retracting the kite, up to dark red, for the fully powered kite with $u_p = 1$ during the traction phase. Table 2 filters #1 and #2 have been applied.

To make this trend more visible in Fig. ?? a color code is used to indicate the power setting u_p . The smoothing rule described in Section (4.1) is applied to the data. We further assume that the high lift-to-drag ratios of up to $L/D = 12$, visible in Fig. ?? are not physical. In Fig. ?? To identify the cause of the high L/D values, we further exclude data points with a tether force below $F_t = 400$ N are not plotted, which proves that this is the cause for the unrealistically high aerodynamic efficiency values. For low tether tension the model is not valid since it assumes straight tensioned lines and a $F_t < 400$ N (filter #2). For such low tether tensions the assumptions of a straight tether and quasi-steady state of the kite. Both should be doubted for low registered tether forces, since inertia of the kite and KCU can not be neglected with respect to such a low force. This is why flight state are not valid anymore, which can lead to substantial measurement errors. Excluding data points with low tether force are not plotted for all further plots $F_t < 400$ N in fact eliminates many of the unphysically high L/D values.

— Effect of steering on the lift-to-drag ratio. Red color indicates a turning maneuver with strong steering line deflection.

In Fig. ?? L/D values are plotted with a color code indicating the strength of the steering input. Yellow and red colors indicate a very strong steering maneuver. It is visible that this coincides with the occurrence of low tether force and the extreme values of the lift-to-drag ratio L/D . To compare the experimental data with aerodynamic kite models we look at straight flight segments only and exclude the effect of deformation during turning. That's why the data points with strong steering input are filtered. This yields the plot in Fig. ?? where all filters described in Table 2 are applied.

In all plots we see that The diagrams of Figs. 13 and 14 show that for an increasing power setting u_p u_D the angle of attack α and also the lift-to-drag ratio increases. The maximal lift-to-drag ratio of about $L/D = 5$ lies at an L/D increases. A low angle of attack of $\alpha \in [7, 10]$ results in a low lift force and therefore a low force ratio. The maximum of about $L/D = 5$ occurs in the range $5^\circ < \alpha < 10^\circ$ and is only reached when the kite is at its highest power setting $u_p = 1$ for $u_D = 1$. For higher angles of attack L/D is lower again. For the plotted lift-to-drag ratio over the angle of attack we obtain the same trend we would expect for a conventional airfoil or aircraft. Low angles of attack produce small lift and therefore a low L/D , after reaching a maximum for an angle of attack of usually around $\alpha = 8^\circ$ the lift-to-drag ratio drops again for higher values because of increased drag. The same trend force ratio decreases again because of the substantially increasing drag force. The measured dependency follows the same general trend as for conventional aircraft wings and was already observed in flight data analyzed by van der Vlugt et al. (2013).

From Fig. ?? we see that steering maneuvers lower the aerodynamic efficiency. Figure 15 shows the temporal evolution of u_D and L/D . For the same power setting u_p , lift-to-drag ratios are significantly lower in traction and transition phase when the kite's steering is activated. The cause can be either the during pumping cycle operation. During the traction phases with $u_D = 1$

Figure 15. Evolution of the lift-to-drag ratio during pumping cycle operation.

we observe periodic drops to force ratios $L/D < 4$. The drops are correlated with the turning maneuvers and are caused by the steering-induced deformation of the kite when the steering line length is changed or the flow vector coming from the side as a result of rotation and cornering of the kite. As both are happening at the same time it is hard to determine which is the dominant cause, possibly both factors lead to an increase in drag and consequently a lower wing and the additional drag component of the required side force (Fechner et al., 2015). To investigate the effect of the steering on the entire data set, we color in Fig. 16 the measured L/D value. Also there is data by the steering intensity. We can recognize that very strong turning maneuvers

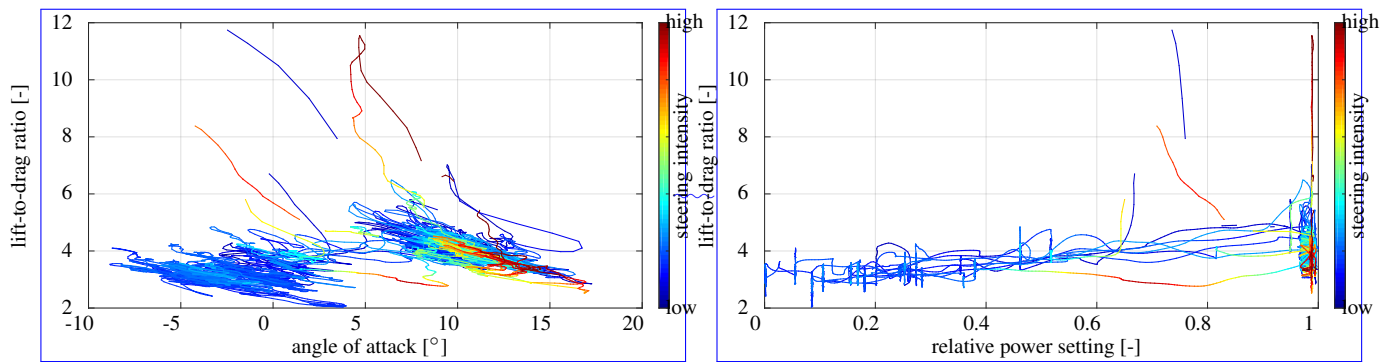

Figure 16. Measured lift-to-drag ratio L/D of the kite plotted over the angle of attack α of the wing and colored by the relative power setting u_p , colored by the steering intensity, ranging from blue, for no steering, up to yellow and red, for strong steering actuation during turning maneuvers. Table 2 filters #1 and #2 have been applied.

coincide with a low tether force and extreme force ratios. During the traction and transition phases, the lift-to-drag ratio for a specific power setting is significantly lower when the steering system is active. This has been shown also in Oehler et al. (2018). Next to the described effects of deformation and steering-induced drag, there is also a feedback loop because an increasing drag lowers the L/D value which will increase α_t which in turn increases α_t and to a certain extent also α . For higher L/D values we find a lower L/D value again. Figure ?? shows the evolution of L/D over time, together with the power setting u_p . It is visible again, that changes of the power setting u_p have a dominant effect on L/D . During traction phase all drops below $L/D = 4$ occur at the same time than steering maneuvers. This is due to the deformation of the kite and the additional drag that makes steering possible (Fechner et al., 2015). For a comparison with aerodynamic models which assume straight flight the exclusion of all data points with a strong steering command is necessary. further.

Evolution of the lift-to-drag ratio during pumping cycle flight.

4.3 Comparison with aerodynamic models

Two real time capable models for simulation of a Ruppert (2012) and Fechner et al. (2015) present two different real-time-capable models for the dynamic simulation of pumping kite power system were developed by Ruppert (2012) and Fechner et al. (2015). The aerodynamic models they use were modified from experimental data or two dimensional sail wing experiments. Fechner writes that they made experience based modifications to the aerodynamic models. In both cases major model systems. In both approaches the aerodynamics of the kite is described by $C_L(\alpha)$ and $C_D(\alpha)$ correlations that have been derived from existing measurement data of two-dimensional sail wing sections. According to the authors, major adjustments were required to align simulation results with the fit the simulated flight behavior of the kite to measured reference trajectories. Both dynamic models predict the flight experiments. Their justification is that they produce good simulation results and can trace the real flight path and power production in many flight situations. Both authors were not primarily focusing on aerodynamics of the kite but more on developing a model that works conveniently for a simulation of the flight path and with reasonable accuracy for a broad range of operational conditions and are thus suitable for optimization of kite control.

Filters applied to the data points of the lift-to-drag ratio: filter reason visible effect moving average oscillation GS; balance
30 reduces spread over 2.5s dynamic effects to during reel-in make quasi-steady assumption applicable $F_t > 400N$ model limitation
delete outliers exclude steering strong deformation delete outliers

As they both use different definitions for Two different definitions of the angle of attack α , we have to assume an offset in this
angle. Fechner et al. (2015) defines are used. Fechner et al. (2015) measure the angle from the center chord to the flow vector
as angle of attack, Ruppert (2012) uses relative flow velocity vector, while Ruppert (2012) measures it from the orientation
of the inertial measurement unit (IMU) mounted on the kite towards the flow vector. Both values are hard to reproduce in a
following measurement campaign as the kite center chord orientation is generally unknown and only estimated, wing-mounted
IMU. Both definitions are difficult to reproduce experimentally for subsequent measurement campaigns because the orientation
of the center chord is a virtual geometric property and can only be estimated, while the IMU is mounted with Velcro tape on
5 a strut of the kite which makes a reproducible orientation difficult on one of the inflatable struts with Velcro® tape which
introduces a considerable degree of uncertainty, even when using the same kite.

To compare their models with the measured data of this experiment, both curves are transformed to have their maximal
the two existing sets of aerodynamic correlations with our measurement data we first need to eliminate the offsets introduced
by the different definitions of α . For this purpose we shift the L/D value at $\alpha = 7.5^\circ$ such as in the measured data instead
10 of $\alpha_{L/D,max,Ruppert} = 12.5^\circ$ and $\alpha_{L/D,max,Fechner} = 16^\circ$. correlations of Ruppert (2012) and Fechner et al. (2015) in the
 α -range such that the maxima occur at $\alpha = 7.5^\circ$, which is where the maximum average L/D of our data set is located.
For reference we note that the maxima of the unshifted correlations occurred at $\alpha = 12.5^\circ$ (Ruppert, 2012) and $\alpha = 16^\circ$
(Fechner et al., 2015).

As stated above the lift-to-drag ratio decreases during turning maneuvers because of the additional drag of the wing tips. This
15 can be clearly recognized from the data plotted in Fig. 15, which exhibits strong variations when flying crosswind maneuvers
during the traction phases. On the other hand, the existing aerodynamic correlations have been derived for a wing in straight
flight, with symmetric steering input. Ruppert (2012), for example, has excluded from his analysis data points that were
associated with strong asymmetric steering input. We have applied a similar filtering procedure to our data. In Fig. 17 we
compare the filtered data with the existing aerodynamic correlations.

Fechner et al. (2015) states that during steering maneuvers the L/D values are lower due to increased drag at the tips.
20 Therefore the aerodynamic curves are only valid for straight flight. Ruppert (2012) in the same way excluded data points The
correlation of Ruppert (2012) is mainly based on five data sets acquired with a LEI V2 kite with strong steering inputs from
his model for the aerodynamic efficiency. From the data in Fig. ?? it is apparent that a turning kite and a kite flying straight do
not have the same L/D values. For this reason 25 m^2 wing surface area, as shown in Fig. 1 (right), and one data set acquired
with a smaller LEI Hydra V5 kite, as used for the diagram in Fig. ?? only data points without excessive use of the steering
capability are plotted. All the filters described in Table 2 are applied. Combining all these filters on the scatter plot from Fig.
?? yields Fig. ?? We 7. On the other hand, the correlation of Fechner et al. (2015) is based on aerodynamic models for stalled
5 and unstalled airfoils from Spera (2008), with additional experience-based modifications for achieving a better fit with the
aerodynamics of a LEI tube kite. For system level modeling, van der Vlugt et al. (2019) distinguish between a large (LEI V3)

Comparison of measured lift-to-drag ratio with the aerodynamic models of Fechner et al. (2015) and Ruppert (2012).

Figure 17. Comparison of measured lift-to-drag ratio with existing aerodynamic correlations. Table 2 filters #1, #2 and #3 have been applied.

and a small (LEI Hydra V5) kite, using lift-to-drag ratios of 3.6 and 4.0, respectively, during the traction phases as opposed to 3.5 and 3.1, respectively, during the retraction phases.

Overall, we find a reasonable agreement of the measured data points with the aerodynamic models. Both models between our measured data and existing aerodynamic characterization attempts. The correlations of Ruppert (2012) and Fechner et al. (2015) slightly overestimate the lift-to-drag ratio and have high values of $L/D > 4$ even for angles of attack exceeding $\alpha > 15^\circ$. This is caused by their assumption that the kite flies at these high angles. We found that the angles of attack the kite is flying at are lower and do usually not exceed $\alpha = 15^\circ$. The two states of the depowered ($u_p < 0.5$) consistent with the common assumption of a high angle of attack during the traction phase (van der Vlugt et al., 2013). Our measurements show, however, that the angle of attack is lower and generally does not exceed $\alpha = 15^\circ$. The lift-to-drag data proposed by van der Vlugt et al. (2019) for traction and retraction phases corresponds very well with the average lift-to-drag ratios measured in these phases. The depowered kite ($u_p < 0.5$) and the powered kite ($u_p = 1$) show different trends. We can see from Fig.?? The data plotted in Fig. 14 indicates that the lift-to-drag ratio of the depowered kite wing depends mainly on the power setting u_p . Changes of u_p , while the effect of the angle of attack don't have a strong effect in this flight regime. For the powered kite where the power setting is kept constant at $u_p = 1$ is only minor. In contrast to this, the force ratio of the powered kite depends mainly on the angle of attack with L/D decreasing for increasing α .

With Eq. (4) we have formally separated three fundamental contributions to the angle of attack is dominating the aerodynamic efficiency. The higher it is, the lower the aerodynamic efficiency is.

The difference in lift-to-drag ratio of the kite for different power settings is large as can be seen in Fig.?.?. The wing twist of the kite as well as its anhedral angle is changed when the kite is depowered. Due to the complex and large scale deformation of the kite it seems justified to deal with the powered and depowered kite as two different wings rather than seeking to find one aerodynamic model with L/D only depending on α of the wing. While the tether angle of attack α_t and the line angle λ_0 represent the contributions due to flight motion and pitching of the entire kite with respect to the tether, the depower angle α_d , which is linked to the relative power setting u_p by Eqs. (5) and (6), also causes a complex deformation of the bridled membrane wing (see Sect. 3.2). The spanwise twisting and bending has a strong secondary effect on the aerodynamics of the wing and

accounting only for the dependency on α leads to considerable uncertainty of the measured aerodynamic characteristics. This effects is one of the contributing factors for the broad spreading of the data in Fig. 17. For this reason, we recommend to keep the relative power setting as a separate influencing parameter, next to the angle of attack. The idea of (Fechner et al., 2015) and (Ruppert, 2012) to combine power setting and measured angle of attack in one variable is still used in Fig. ??, to improve the aerodynamic characterization of a pumping cycle AWES over the whole flight envelope. In fact, the transition from powered to depowered state of the wing should be regarded as a sequence of different wings.

4.4 Lift coefficient C_L

The tests considered in this study are based on a constant force control strategy for the traction phases, with a set value $F_{t,0} = 3.25$ kN. Whenever the actual tether force F_t drops below this value, the ground station reduces the reeling speed $v_{t,r}$ when the force exceeds this value, it increases the reeling speed. This control strategy ensures that the aerodynamic loading of the system is limited despite operating in a fluctuating and varying wind environment.

In Fig. ?? the lift coefficient is plotted against the measured apparent flow velocity for the kite in traction phase with the criteria that the value of the traction force is above $F_t = 3.18$ we plot the measured lift coefficient C_L of the kite as a function of the relative flow velocity v_a , colored by the heading. The diagram only includes data from the traction phases and when

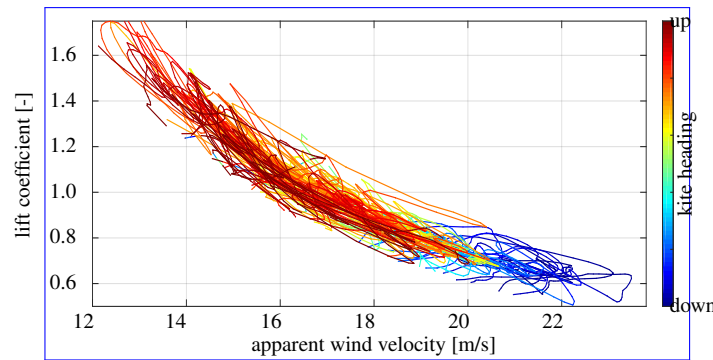

Figure 18. Measured lift coefficient C_L of the kite as a function of the relative flow velocity v_a and colored by the heading. The heading range from down to up covers both heading angle ranges $180^\circ > \psi > 0^\circ$ and $180^\circ < \psi < 360^\circ$ equally (see Fig. 6).

10 $F_t > 3$ kN. Flight situations which do not meet this criteria mark transitions to /from the reel-in period condition are, for example, the transitions to and from the retraction phase or sharp turning maneuvers. Dependency of the kite's equilibrium speed on the kite's heading χ . The kite is controlled to deliver a constant tether force of $F_t = 3.25$ kN. Because of Eq. (15) and the constant force condition all points lie on a curve that fulfills

15 $C_L \cdot v_a^2 = const.$

control the data points are correlated by

$$C_L v_a^2 = const. \tag{19}$$

The constant force control strategy requires that the kite delivers a constant traction force of $F_{t, reel-out} = 3,25 \text{ kN}$ at the ground station throughout the traction phase, regardless of atmospheric wind and flight situation such as elevation and heading.

20 This goal is achieved by controlling the reel-out speed. Figure 18 clearly shows how the flight motion of the kite v_t . Whenever the traction force drops below $F_{t, reel-out}$, v_t is reduced, if it exceeds this value, v_t is increased. The interest of Fig. ?? is the fact that the kite chooses different flight conditions to produce the commanded $F_{t, reel-out}$. When the kite is flying downward, it flies faster with a lower lift coefficient and angle of attack. When flying upward, the kite flies slower with a higher lift coefficient and higher angle of attack. This can be explained by the effect of the kite's weight (see Fig. ??). When the balance that varies along the crosswind maneuvers to maintain the commanded tether force $F_{t,0}$. As a result of gravity, the kite flies faster, with lower α and C_L on trajectory segments with a downwards component, while it flies slower, with higher α and C_L on segments with an upwards component. Because of the constant force control strategy is applied v_a show a strong adverse trend towards, the relative flow velocity v_a exhibits an inversely proportional behavior to the angle of attack α and C_L . The adverse trend of angle of attack and apparent flow velocity v_a the lift coefficient C_L . The inversely proportional correlation of α and v_a can also be observed in the plot of Fig. ?? recognized in Fig. 12.

During traction phase the kite flies with different angles of attack but

10 Van der Vlugt et al. (2019, Sect. 2.4) show that the angle of attack of a massless kite with constant power setting does not vary along its flight path through a constant uniform wind field. The described effect of gravity and the natural wind environment induce a variation of the angle of attack, although the power setting is kept constant at $u_p = 1$. This way the change of C_L $u_p = 1$ when flying crosswind maneuvers. Because of the constant power setting, the wing is not deforming and the variations of C_L and L/D can be linked to the difference in α as the kite is not being actively deformed by changing u_p , attributed solely

15 to changes in of the angle of attack.

Figure 19 shows the measured lift coefficient C_L as a function of the angle of attack, colored by the heading of the kite. Figure ?? shows the lift coefficient with the angle of attack. The black points are the mean values for different headings

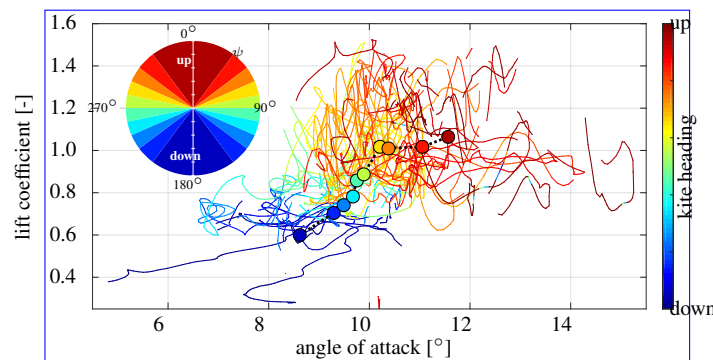

Figure 19. Lift Measured lift coefficient C_L plotted over C_L of the kite as a function of the angle of attack α . Black dots represent, colored by the mean values for different headings heading.

χ . Thereby the ten black circles each represent the average of data points with a similar heading To better differentiate the effect

of the heading, we subdivide the range from pointing downwards to pointing upwards into 10 classes. The heading classes are equidistant in $\cos \psi$, i.e. $\Delta \cos \psi = 0.2$, as indicated by the circular legend in Fig. 19. Per class we compute the average data point and display this as a symbol according to the color legend. The leftmost point is thus dark blue data point with the lowest angle of attack thus represents the average of all points where the kite's heading is most measured flight conditions with a heading that is most closely aligned with the gravity vector which are shown in dark blue in Fig. ?? . Although the data is spread over a wide range, there are

Despite of the filtering, Figs. 17 and 19 show still a considerable dispersion of the measured data. The various idealizations required to model the flexible membrane kite system and the assumption of quasi-steady flight with negligible inertial effects contribute to that as well as the fact that the evaluated pumping cycles differed in flight path, wind conditions and many other parameters. Yet, we can recognize two clear trends visible of the averaged data:

- For higher angles of attack the lift coefficient is higher, increases with the angle of attack, and
- When flying upward the kite flies at a higher the angle of attack and lift coefficient are higher when flying upwards.

The first one is the common behavior for most aerial vehicles. The first trend reflects the common aerodynamic characteristics of a wing, while the second trend is caused by the second one originates in the constant force control strategy and was already observed by Oehler (2017). The average lift coefficient plotted in Fig. 19 exhibits a steep slope for lower angles of attack. The slope of the lift coefficient with increasing angle of attack is steep. In Fig. ?? the lift coefficient increases from 0.7 at $\alpha = 9^\circ$ to 1.0 at $\alpha = 12.5^\circ$. At $\alpha = 9^\circ$ we measure an average value $C_L = 0.7$ while at $\alpha = 12.5^\circ$ this value has risen to $C_L = 1.0$, which is close to the ideal case of a two dimensional two-dimensional lifting surface. Increased camber For wings with low aspect ratio, such as the considered soft kite, we generally expect a more gentle slope of the lift coefficient. The increasing camber and flattening of the wing for higher angles of attack and flattening of the kite are two mechanisms that can contribute to this steep slope. The kite flattens for a higher C_L and therefore produces more lift. Since for the calculation of the lift coefficient (see Sect. 3.2 and Fig. 9). Since we use a constant reference surface this would in return increase C_L . During traction phase we do not change wing surface area in Eq. (15) these mechanisms increase the lift coefficient.

Because the power setting of the kite and can therefore is kept constant during the traction phase we can not actively control α . The the angle of attack it flies at is the result of the of the wing. Instead, the angle results from the quasi-steady force equilibrium of the kite. The parameter with the biggest and is thus affected by the varying gravitational force contribution and the wind environment. Our analysis shows that for operation with constant force control the heading of the kite has the strongest influence on the angle of attack is found to be the heading of the kite χ . When it is flying upward during crosswind maneuvers. When the kite is flying upwards, drag and weight are almost aligned, for downward flight, they point in different gravitational force are pointing in similar directions, while for downwards flight, both forces point in opposite directions. This causes the differences in apparent flow speed (see Fig. ??) and relative flow velocity in Fig. 18 and in angle of attack (see Fig. ??) in Fig. 19.

5 Conclusions

30 ~~The aerodynamic efficiency L/D . In this study we present a method to determine the lift-to-drag ratio and lift coefficient of a soft kite can be determined during dynamic flight maneuvers with a flow direction sensor during flight operation by in situ measurement of the relative flow. Tailored towards a kite system with suspended control unit, the flow sensor is installed in the bridle lines. The power setting u_p and the power lines and independently measures the magnitude of the relative flow velocity, the sideslip angle and an orthogonal inflow angle from which the angle of attack of the wing is derived. The effect of gravity on the individual kite components is taken into account in processing the data as well as the aerodynamic drag of kite control unit and measurement setup. Further included are a smoothening procedure to remove the effect of low frequency oscillations induced by the ground station, and filtering procedures to remove the effects of too low tether tension and high steering intensity.~~

We distinguish three fundamental contributions to the angle of attack ~~are found to play the most important role for the~~ of the wing: the tether angle of attack α_t , which is related to the flight motion of the kite, the line angle λ_0 , which characterizes the pitch of the entire kite relative to the tether, and the depower angle α_d , which characterizes the pitch of the wing relative to the kite due to depower actuation. While λ_0 is influenced by the interaction of the tether force and the gravitational and aerodynamic forces acting on the individual kite components, α_d is inversely related to the relative power setting u_p and correlated with a spanwise twisting and bending of the bridled membrane wing.

The measurements show that the lift-to-drag ratio ~~Data shows that lift-to-drag ratio grows with the power setting u_p . The highest lift-to-drag of the kite increases with the relative power setting. For straight flight the maximum ratio is reached for straight flight with low at an angle of attack and low lift coefficient C_L of 8° and a moderate lift coefficient.~~ Steering maneuvers have a negative effect on the aerodynamic efficiency. ~~In the observed flight the reduce the lift-to-drag ratio. For the investigated data set the variation of the angle of attack varies only by around five degrees during traction phase. Angle of attack and apparent flow velocity show adverse trends when the tether force stays constant. During traction phase the kite shows a high lift coefficient for high angles of attack. The kite's weight and heading have a considerable effect on the kite's during the traction phases is limited to about 8° . Because of the constant force control operation of the ground station, the angle of attack is inversely related to the relative flow velocity. During the traction phase, the angle of attack and lift coefficient. When the kite is flying upward it flies at lower speed and higher the lift coefficient are both increased, yet strongly influenced by the effect of gravity, which varies with the heading of the kite. When flying upwards, the flight speed of the kite decreases and the angle of attack increases to compensate for gravity. the effect of gravity, when flying downwards, the speed increases and the angle decreases.~~

25 ~~Combining power setting and measured~~ We find that the aerodynamic characteristics of the bridled membrane wing do not only depend on the angle of attack in one variable which defines the aerodynamic efficiency is not accurate over the whole flight envelope. Both the power setting and the angle of attack are essential variables for the aerodynamic efficiency. A change in power setting causes a complex deformation of the kite, the, as common for rigid wings, but also on the level of aerodynamic loading. For the investigated C-shaped wing, we observe, for example, that increasing the loading causes the

30 wing to flatten which enlarges the projected area and amplifies the effective aerodynamic force. Because the loading is actively controlled by the relative power setting, we can use this parameter to correlate the effect of the loading on the aerodynamic characteristics. How exactly the power setting affects the wing shape depends strongly on the layout of the bridle line system. Our measurements show that accounting only for the dependency on the angle of attack ~~changes the flow field to affect the aerodynamic coefficients~~ variation, as commonly done, leads to a considerable uncertainty of the aerodynamic characteristics. Establishing a dependency on both or dealing with the powered and depowered kite as two different wings seems necessary for a good aerodynamic model. We expect that using the relative power setting as a secondary influencing parameter will improve the aerodynamic characterization of a pumping cycle AWES ~~over the whole flight envelope.~~

Using a Kalman filter, as shown by Schmidt et al. (2017), could help to increase the accuracy of the measured data and the actual state of the system by including knowledge about system behavior and the data of other onboard sensors, such as the inertial measurement unit. Another possible improvement of the analysis would be to retrofit the power and steering lines with force sensors, to assess the aerodynamic load distribution on the wing.

5 ~~The~~ The effect of the kite control unit ~~has a considerable effect~~ is considerable as it contributes about 40% of the ~~airborne total kite~~ mass and 10% of the ~~system drag. Having it suspended only~~ drag. Because of the suspension in the steering lines ~~allows it to perform unpredictable movements especially it can exhibit unpredictable movements, particularly~~ during turns and when ~~the~~ tether force is low during ~~reel-in~~ retraction phase. This adds uncertainty to the calculated orientation of the kite. Moving the ~~KCU into control unit towards~~ the bridle point and connecting it to ~~both~~ power and steering lines could ~~potentially~~ avoid this problem ~~and results in an easier bridle model (Fig. ??).~~

Data availability. The data set used for this study is available from <https://github.com/rschmehl/wes2018>. Data sets of current test flights can be requested freely for research purposes by emailing Kitepower B.V. at data@kitepower.nl.

Appendix A: ~~Correction for flow~~ Flow velocity induced by the kite with lifting line theory wing at the measurement location

5 To estimate the aerodynamic effect on the relative flow at the measurement location below the wing we introduce a lifting line approximation of the C-shaped wing, as depicted in Fig. A1.

~~In Fig. A1 the kite is flying out of the plane, the induced velocity v_{ind} in flight direction can be calculated using potential flow theory and the Biot-Savart law.~~

$$v_{ind} = \frac{\Gamma}{4\pi r} (\cos(\alpha_1) - \cos(\alpha_2))$$

10 ~~The induced velocity is the sum of induction by the circulation of the middle section Γ_T and the tip section.~~ The center section is represented as a straight vortex segment of finite length with circulation Γ_1 , while the tip sections are represented by straight

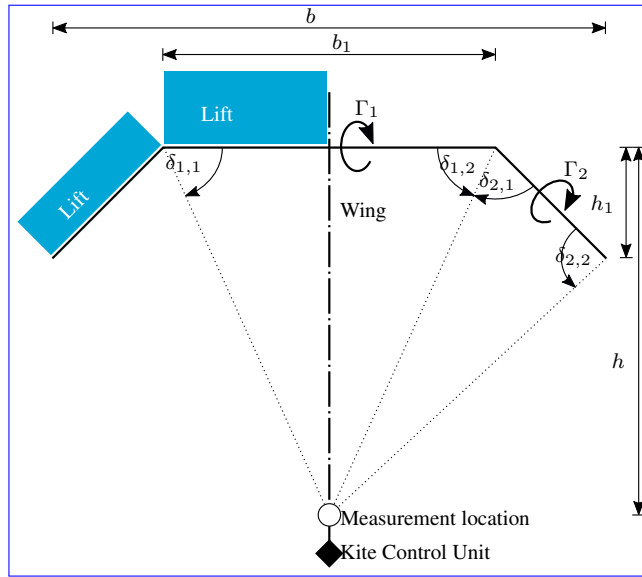

Figure A1. Simplified kite model with sensor position to apply Front view of the lifting line theory model of the kite, flying towards the reader.

segments with circulation Γ_2 . Γ_1 and Γ_2 can be calculated with the values from Table A1.

$$v_{ind,sensor} = v_{ind,1} + v_{ind,2}$$

15 The contribution of a vortex segment i to the induced velocity v_{ind} at the measurement location is calculated by the Biot-Savart law

$$v_{ind,i} = \frac{\Gamma_i}{4\pi r_i} (\cos \delta_{i,1} + \cos \delta_{i,2}), \quad (A1)$$

For symmetry reasons we calculate only one half and double the effects since both sides have the same effect on the induced velocity. For the where r_i is the perpendicular distance between the measurement location and the vortex segment, $\delta_{i,1}$ and $\delta_{i,2}$ are the angles between the segment and the (dotted) lines connecting its ends with the measurement location. Following the superposition law of potential flow, the velocity induced by the three vortex segments at the measurement location is calculated as

$$v_{ind} = v_{ind,1} + 2v_{ind,2}. \quad (A2)$$

Because of the symmetric layout of the wing with respect to the measurement location, we first calculate the velocity induced by one wing half and then double this effect. Using the geometric parameters defined in Fig. A1 we can determine the line angles δ and from these calculate the velocity induced by the middle section we obtain

$$v_{ind,1} = 2 \frac{\Gamma_1}{4\pi h} \cos(\tan^{-1}(\frac{2h}{b_1})),$$

center section

$$v_{ind,1} = 2 \frac{\Gamma_1}{4\pi h} \cos \left[\arctan \left(\frac{2h}{b_1} \right) \right], \quad (A3)$$

5 ~~for the two tip sections we get~~

$$v_{ind,2} = 2 \frac{\Gamma_2 \sqrt{2}}{4\pi(h + \frac{b_1}{2})} \left(\cos \left(\frac{3}{4}\pi - \tan^{-1} \left(\frac{2h}{b_1} \right) \right) - \cos \left(\frac{3}{4}\pi - \tan^{-1} \left(\frac{2(h-h_1)}{b} \right) \right) \right).$$

and by each tip section

$$v_{ind,2} = \frac{\sqrt{2}\Gamma_2}{4\pi(h + \frac{b_1}{2})} \left\{ \cos \left[\frac{3}{4}\pi - \arctan \left(\frac{2h}{b_1} \right) \right] - \cos \left[\frac{3}{4}\pi - \arctan \left(\frac{2(h-h_1)}{b} \right) \right] \right\}. \quad (A4)$$

10 ~~The freestream velocity v_∞ . The apparent flow velocity v_a at the measurement location is the sum of measured apparent flow velocity v_a and v_{ind} . For the geometry of the used kite and sensor the induced velocity stays smaller than $v_{ind} < 0.2ms^{-1}$. The induced angle of attack at the sensor's position α_i when considering the induced downwash of the kite's tip vortices stays below $\alpha_i < 0.6^\circ$. the freestream velocity v_∞ and the induced velocity v_{ind} . Using the values listed in Table A1 we calculate an induced velocity $v_{ind} < 0.2$ m/s. Because of their small magnitude and to simplify our calculations in this paper the measured~~

Table A1. ~~Geometric model~~ Model parameters of ~~V3 kite~~ the LEI V3 kite for ~~lifting line~~ lifting-line theory

b	b_1	h	h_1	$\frac{\Gamma_2}{\Gamma_1} \Gamma_2 / \Gamma_1$	L	$\overline{v_\infty} \overline{v_\infty}$
height 7m <u>8 m</u>	4m <u>4 m</u>	8.5 m	1.52 <u>m</u>	$\frac{5}{8}$ <u>5/8</u>	3250N <u>3250 N</u>	18ms⁻¹ <u>18 m/s</u>

15 ~~apparent flow variables are considered always~~ Considering the induced downwash due to the wing tip vortices, the induced angle of attack at the measurement location is $\alpha_{ind} < 0.6^\circ$. Accordingly, the effect of the induced velocity on the relative flow measurements is negligible and the apparent flow velocity can be considered to be equal to the free stream velocity. For bigger kites that have an increased surface area and much higher pulling larger kites with much higher tether forces the induced velocity plays a bigger role and must be considered for a precise measurement might play a more important role and should thus be taken into account for precise measurement of the relative flow.

Competing interests. Roland Schmehl is co-founder of and advisor for the start-up company Kitepower B.V. which commercially develops a

5 100 kW kite power system and which provided their test facilities and staff for performing the in situ measurements described in this article. Both authors are financially supported by the European Union's Horizon 2020 project REACH, which also provides funding for Kitepower B.V.
