

Design Procedures and Experimental Verification of an Electro-Thermal De-Icing System for Wind Turbines

David Getz* and Jose Palacios†

Pennsylvania State University, University Park, Pennsylvania 16802

There has been a substantial growth in the ~~total~~ wind energy ~~power~~ capacity worldwide. ~~Icing and icing~~ difficulties have been encountered ~~for in~~ cold climate locations. Rotor blade icing has been recognized as an issue and solutions to mitigate ~~its~~the effects have been identified. Wind turbines are adapting helicopter rotor and propeller ice protection approaches to reduce aerodynamic performance degradation related to ice formation. Electro-thermal heating is one of the main technologies used to protect rotors from ice accretion and it is one of the main technologies being considered to protect wind turbines. In this research, the design process required to develop an ice protection system for wind turbines is discussed. Three icing conditions were considered: Light, Medium and Severe. Light icing conditions were created using clouds at -8°C with a 0.2 g/m^3 liquid water content (LWC) and water droplets of $20\text{ }\mu\text{m}$ median volumetric diameter (MVD). Medium icing condition clouds had a LWC of 0.4 g/m^3 and $20\text{ }\mu\text{m}$ MVD, also at -8°C . Severe icing conditions had an LWC of 0.9 g/m^3 and $35\text{ }\mu\text{m}$ MVD at -8°C . The design approach relies on modeling and experimental testing. Electro-thermal heater system testing was conducted at The Adverse Environment Rotor Test Stand at Penn State. ~~Wind,~~ where wind turbine representative airfoils protected with electro-thermal de-icing were tested at representative centrifugal loads and flow speeds. The wind turbine sections were $\frac{1}{2}$ scale models of the 80% span region of a generic 1.5 MW wind turbine blade. A sample wind turbine configuration was selected to describe the design process. ~~A and a~~ 1.5 MW wind turbine was chosen. The icing cloud impact velocity was matched to that of a 1.5 MW wind turbine at full power production. Initially, ice accretion modeling was ~~conducted to provide an initial prediction of~~performed to provides the power density required to debond accreted ice at a set of icing conditions. Then, ice accretion thickness gradients along the span of the rotor blade for light, medium and severe icing conditions were collected experimentally. Given a pre-determined maximum power allocated for the de-icing system, heating zones were introduced along the span and the chord of the blade to provide the required power density needed to remove the accreted ice. The heating sequence for the zones started at the tip of the blade, to allow de-bonded ice to shed off along the span of the rotor blade. ~~Given the~~The continuity of the accreted ice along the ~~bladed~~blade span, ~~means that when using a portioned~~ heating ~~a~~zone, ice could de-bond ~~the ice~~over that specific zone, but the ice formation could ~~not detach from the blade as it would be~~remain attached cohesively ~~as it is~~ connected to the ice on the adjacent inboard zone. To prevent such cohesive retention of ~~interface~~ debonded ice, the research determined the minimum ice thickness required to shed the accreted ice mass with the given amount of power availability by not only melting the ice interface over the zone, but also creating sufficient tensile forces ~~due to centrifugal loads~~ to break the cohesive ice forces between two adjacent heating zones. The quantified minimum ice thickness to overcome ice cohesive forces were obtained for ~~all identified~~the tested icing conditions. The experimental data was critical in the design of a time sequence controller that allows consecutive de-icing of heating zones along the span of the wind turbine blade. Based on the experimental and modeling efforts, de-icing a representative 1.5 MW wind turbine with a 100 kW power allocation, required four sections along the span, with each heater section covering 17.8% span and delivering a 2.48 W/in^2 (0.385 W/cm^2) power density. The time sequences for the controller required approximately 10 minutes for each cycle.

Nomenclature

- A_{CS} – Cross-sectional area of accreted ice shape
 CF_{AERTS} – Centrifugal force experience in AERTS
 CF_{WT} – Centrifugal force experienced on the wind turbine
 L_{AERTS} – Span-wise length of the heater test section in AERTS
 L_{WT} – Span-wise length of the heater section on the wind turbine
 m_{AERTS} – Ice mass on the heater test section in AERTS
 m_{WT} – Ice mass on the heater section of the wind turbine
 ρ – Density of glazed ice in g/cm^3
 Ω_{AERTS} – Rotational velocity of the rotor blade in AERTS facility
 Ω_{WT} – Rotational velocity on the wind turbine rotor blade
 r_{AERTS} – Radius from axis-of-rotation to center of heater section
 r_{WT} – Radius from axis-of-rotation to beginning of heater section

I. Introduction

Conventional energy like coal, natural gas and oil have gradually become a source of concern due to their environmental impacts. Wind energy has been used to generate electric power for over 100 years and the industry boomed during the oil crisis in the 1970s ¹-(Ackerman, 2002). In recent years, many developers are investing in wind farms in cold climate regions, because of the ~~areas being remote, areas having~~ favorable wind conditions, ~~and~~ higher air densities ~~and being remote~~. Among all the renewable sources, wind power has promising commercial prospects with the ability to produce large-scale electricity generation². ~~Many countries have adopted this energy generation making wind market expand rapidly. Countries like China, Germany, United States, Denmark, Turkey and Spain have made substantial contributions towards the progression of wind energy.~~³⁻⁴. In the last decade, the average annual growth for the world's wind power generation is approximately 30%. The global wind power capacity installed between 1990 and 2015 is shown in Figure 1. According to the World Energy Association, it is estimated that the capacity will reach 425 GW by 2015.⁵⁻⁶ generation. The wind turbine power capacity installed from 1990 to 2015 is summarized in Figure 1.

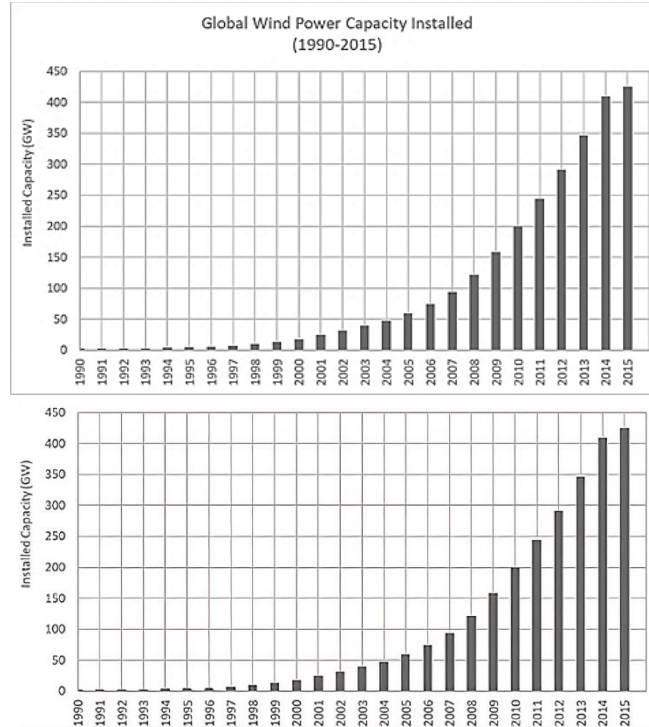

Figure 1: Global wind power capacity installed, GW, 1990-2015 ⁵-(ABS Energy Report, 2010).

In 2009, the U.S. had installed 10GW with a total installed capacity of 40.2GW. It is estimated that wind energy will generate 20% of the US electricity in 2030. Currently, it produces 2% of the nation's ~~electricity~~⁷-electricity (US Global Wind Energy Council, 2011). In 2010, China surpassed the U.S. as the world's leader of wind power⁸-(Xu, 2010). This is no surprise considering China's installed capacity doubled each year since 2006. The installed capacity of the leading wind power countries is demonstrated in Figure 2.

Figure 2: Installed wind power capacity in leading ~~countries~~⁷⁻¹¹-countries (US, PR China, Germany, India and Spain Global Wind Energy Council, 2011).

Most wind turbines experience hazardous icing events in cold climates. ~~The, and the~~ accumulation of ice on the wind turbine blade modifies the blade geometry and ~~degradedegrades~~ the aerodynamic performance. The estimated loss of the total annual energy production (AEP) can be approximately 20% ¹²⁻¹⁴ (Lamraoui, et al., 2014). Severe icing conditions cause rotational torque to decline to zero and the turbine is forced to shut down. Wind turbines also ~~are stoppedstop~~ under icing conditions that cause heavy vibrations, because these vibrations promote ice shedding, which can lead to imbalance forces that could damage the hub of the wind turbine and ~~could~~ pose threats to the surrounding environment due to ballistic shedding events ¹⁵⁻¹⁷ (Feng et al., 2012; Lassko et al., 2010; Hockart et al., 2008).

The ice accumulation problem is a complex phenomenon that combines various parameters. The shape of the ice and rate at which it accretes is dependent upon the atmospheric temperature, liquid water content of the cloud, impact velocity, water droplet size, and accretion time. The water content of the cloud is defined by the liquid water content (LWC) in g/m^3 . The water droplet size in the cloud is characterized by the median volumetric diameter (MVD) in μm ¹⁸ (Ruff et al., 1990). The Federal Aviation Administration (FAA) has defined two icing envelopes in the Federal Aviation Regulations Part 25 and Part 29 Appendix C using the MVD, LWC and ambient temperature. Continuous icing proves to be less severe, because the liquid water content ranges from $0.06 \text{ g}/\text{m}^3$ to $0.8 \text{ g}/\text{m}^3$ and the median value diameter of the droplets range from $10 \mu\text{m}$ to $40 \mu\text{m}$ ¹⁹. Typically, the LWC and MVD affect the thickness of the ice shape, while temperature and droplet impact velocity affect the surface roughness and adhesion strength of the ice. Icing envelopes for wind turbine regions have not been officially established.

Icing conditions on wind turbines have led to research in various anti-icing and de-icing ice protection systems (IPS). Anti-icing systems simply keep the rotor blades free from ice. Anti-icing systems consume massive amounts of power because they operate continuously and must protect large areas to prevent risks of water re-freezing in aft locations. De-icing systems allow thin layers of ice to accrete and then rely on centrifugal forces to assist with ice shedding. De-icing systems are less power expensive than anti-icing systems, because they only ~~have to must~~ protect the ice accretion region within ice impingement limits. Also, since accreted ice acts as an insulator, the de-icing system is not subjected to the ~~high~~ levels of convective cooling that an anti-icing system would encounter. De-icing systems attempt to minimize runback water from freezing on the aft section of the blade. ~~The~~ ^{In an anti-icing configuration, the} re-freezing of runback water can be prevented by evaporating the ice interface created by the impingement of super cooled water droplets. In general, the evaporative mode for anti-icing systems require about 5 times more energy to operate, rendering it as too expensive for wind turbines.

The wind turbine industry has ~~borrowedintegrated~~ ice mitigation techniques from the aviation industry. In addition to electro-thermal de-icing, the aviation industry has used active ice protection systems and is working on developing passive techniques. *Passive* ice protection systems consist of coatings that are characterized by low ice adhesion strength. Passive ice-phobic coatings degrade under erosion conditions, which cause them to lose their ice-phobic properties. To date, a fully passive ice protection coating with application to the aviation industry does not exist. Some examples of active ice protection systems are hot-air injection, ultrasonic waves, electro-thermal heaters and pneumatic boots ²⁶⁻³⁰ (Overmeyer et al., 2012; Martin et al., 1992; Flemming, 2003; Botura et al., 2005; Buschhorn et al., 2013).

Electro-thermal ice protection systems are the most common IPSs used due to the simplicity. The system sends electrical current to resistive circuits, which convert electrical energy into thermal energy. These resistive circuits are known as the heating elements. These heating elements are typically adhered underneath the blade skin and coverlay. A simplified schematic of the layers is displayed in Figure 3. Coverlay is a material laminated to insulate the copper conductor. The blade skin is the layer of protection used to prevent surface erosion. The thermal energy converted from electrical energy in the heating elements travel through the layers via conduction.

Figure 3: Simplified electro-thermal IPS schematic.

With latitude coordinates like Canada, electro-thermal ice protection systems are used in Pori and Olostrunturi, Finland. Between 1999 and 2001, Pori's IPS was mainly used for public safety and its power consumption was 1% of the annual production. In extreme events, the IPS used a maximum of 6% nominal power. In Olostrunturi, the IPS used 3.6% of the annual production ^{15,20} (Lasko et al., 2003 and 2005).

This paper concentrates on the design process of an electro-thermal de-icing heater configuration for wind turbines. The conducted research relies on experimental data obtained for an electro-thermal de-icing IPS to determine heater zones and required ice accretion times to promote ice shedding with assistance of centrifugal loads action on the accreted ice.

II. Objectives

This research presents the design process of an electro-thermal ~~ice protection systems (IPS)~~ for wind turbines. The design process begins with predicted values of power density requirements and then relies on experimental results to verify and quantify critical parameters such as ice accretion rates, minimum power densities and required loads to promote cohesive failure between adjacent zones. Representative icing conditions were selected and guided by FAR Appendix C icing conditions typical of aircraft environments. The goal of the ice protection research for wind turbines is to develop methodology to design such de-icing systems. A generic 1.5 MW wind turbine is used to describe the design process. Power limitations on the wind turbine (100 kW) were set as a priority. Shedding times were also enforced (30 seconds from the initialization of the heaters).

228

Firstly, the 2D heater configuration was modeled in LEWICE, a NASA developed ice accretion prediction software²¹.software (Wright et. al., 2008). The modeling results are used to predict ice accretion for varying power densities to the electro-thermal heaters. Secondly, the ice accretion thickness rate must be verified for several icing conditions, as well as the minimum ice thickness needed to promote effective ice shedding and overcome cohesive bonding between span-wise zones. Lastly, power density variation must be explored to quantify the change in shedding times and to enforce the maximum shed time of 30 seconds. To meet this objective, a time sequence controller was designed for the selected icing regimes (light, medium, severe). The conducted research introduces designed guidelines, development, and testing approaches for an electro-thermal de-icing IPS for wind turbines.

The Adverse Environment Rotor Test Stand (AERTS) was designed and constructed at the Vertical Lift Research Center of Excellence at The Pennsylvania State University²¹.University (Palacios et al., 2012). A photograph of the facility equipped with NACA 0012 test blades is exhibited in Figure 4. This photograph shows the QH-50 DASH Hub, 125 HP motor with a built-in torque sensor, Bell Housing with 6-axis load cell, and the collective/cyclic pitch actuators. The hub was donated by Gyrodyne Helicopter Historical Foundation. The QH-50D is a co-axial UAV designed for the Navy in the early 1950's²²1950's. The test stand is surrounded by an octagonal ballistic wall. The surrounding walls of the freezer have dimensions: 6m x 6m x 3.5m.

The chamber is cooled by a 10 HP compressor/evaporator system with controllable temperatures between -25°C and 0°C. The rotor can achieve RPMs up to 1600. The 6-axis load cell measures forces and moments, while the torque sensor monitors the torque provided from the motor. The standard icing nozzles are donated by the NASA IRT and are installed on the ceiling of the chamber. The nozzles are arranged in two concentric rings containing 5 nozzles on the inner ring and 10 nozzles on the outer ring. The nozzle system operates by aerosolizing water droplets with a combination of air and water at precise pressures²³.pressures (Ide et al., 2001). The nozzle calibration curve is presented in Figure 5, which depicts the MVD of the droplet on the y-axis in microns and air pressure differential on the x-axis in pounds per square inch.

B. Blade Configuration

248 The de-icing research conducted for the wind turbine needs to have a testing blade that is representative ~~of that of wind turbine configurations.~~
 249 The selection of the blade shape was done based on the work conducted by Blasco et al. (Blasco, 2015) who conducted detailed aerodynamic analysis
 250 to ensure that the selected scaled bade sections would be representative of a 1.5 MW wind turbine blade. Scaling laws developed by Bond et. al, (Bond
 251 et al., 2004) were used to scale the wind turbine airfoil sections of a full-scale 1.5 MW turbine to sizes that could be spun in the AERTS facility. The
 252 airfoil at the tip of the rotor blade tested has a 72.4 cm (28.5 in) chord with a span of 30.48 cm (12 in). This airfoil represented a 1/2 scale shape with
 253 respect to a representative 1.5 MW wind turbine section at 80% span as described by Blasco et. al. 2015. The DU 93-W-210 airfoil with the carrier
 254 blade amounts to a 139.7 cm (55 in) total span to the rotation axis. The physical dimensions of the rotor test blade are illustrated in Figure 6 ^{24,32}-(Blasco,
 255 2015 and Han 2011). All rotor blade tests were conducted at 0° angle of attack (AoA). Figure 7 is a photograph of the test blade. The leading edge of
 256 the heating elements are protected by an erosion tape with thermistors underneath. The span width of the heaters is slightly oversized in efforts to
 257 prevent ice bridging.

258
259 **Figure 6:** Wind Turbine test blade representative ³²-(Blasco et al., 2015).

260
261 **Figure 7:** Rotor test blade.

262 To represent the centrifugal forces on the accreted ice, representative ice shapes were ~~accreted~~ first accreted as per ice scaling laws provided by
 263 Bond et al., 2004, and the RPM of the AERTS truncated rotor was adjusted to match the centrifugal loads of the full-scale wind turbine at varying span
 264 locations. The specific cloud conditions are described in the next section. A cloud density of 0.917 g/cm³ was selected for the testing. The density value
 265 was selected as it is included in the FAR Appendix C icing envelope and it is also representative of that seen on wind turbines ~~and since it is a~~. Such
 266 water content conditions are typical glaze ice condition ~~that~~ and can be reproduced in other facilities, such as the NASA Glenn Icing Research Tunnel
 267 ²⁵-(Vargas et al., 2005).

268 The cross-sectional area of the ice shape was photographed after each test. A metal hot plate was used to smoothly cut any three dimensional
 269 ice features at the tip of the blade. A perpendicular plane against the 2D ice shape was obtained. The photograph contained a scale used to digitize the
 270 image ³³-(Schneeberger, 2018). The estimated cross-sectional area of the accreted ice was quantified. An example of this digitalization approach is
 271 shown in Figure 8.

Figure 8: Digitized ice shape at -8°C with 0.4 g/m³ LWC.

In this picture, the x and y axes (legs of red leading-edge right triangle colored in red) are 3 cm in length. The estimated ice area of the polygon for the specific test shown is 10.86 cm² and the perimeter of the selected 2D ice area is 29.89 cm. Given density and the length of the protected airfoil (30.48 cm), the estimated ice mass is 303.54 grams. The assumed ice masses were calculated for these experiments as per Equations (1) and (2).

$$m_{WT} = A_{CS} * L_{WT} * \rho \quad (1)$$

$$m_{AERTS} = A_{CS} * L_{AERTS} * \rho \quad (2)$$

The centrifugal forces on the wind turbine and the AERTS facility were equated for a given span location on the full-scale blade. Then the appropriate rotational velocity parameter for the AERTS facility was obtained. Equations (3-5) summarize the process.

$$CF_{WT} = m_{WT} * \Omega_{WT}^2 * r_{WT} \quad (3)$$

$$CF_{AERTS} = m_{AERTS} * \Omega_{AERTS}^2 * r_{AERTS} \quad (4)$$

$$\Omega_{AERTS} = \sqrt{\frac{CF_{WT}}{m_{AERTS} * r_{AERTS}}} \quad (5)$$

The IPS heater configuration must be designed following in the scope of operator requirements and restrictions. Assumptions were made in the design effort presented in this paper. The maximum allowed power for the IPS is set to 100 kW. As it will be shown, the power limitation makes it impossible to protect the entire leading-edge surface of the blades, forcing to partition the de-icing system to ensure that sufficient power densities are available. Based on initial LEWICE models, each turbine blade had to have 4 span-wise heater sections beginning at 26.7% span from the root of the rotor blade and ending at 97.7% span. The span percentages chosen for experimental representation correspond to the beginning of each heater section. A schematic of the heater zones is illustrated in Figure 9. These span partitions allow cohesive bonding of ice between zones to play a role in the ice shedding events. Before the ice accretion reaches a critical thickness, the cohesion strength of the ice exceeds the centrifugal forces to shed the ice layer. Therefore, a minimal ice thickness (mass to be exact as it is linearly related to the load) exist to promote ice shedding (minimum ice thickness such that centrifugal loads are enough to exceed the cohesion strength between zones). Selecting the inner-most span location of each heater section as the point to calculate centrifugal loads for an ice shape is a conservative approach to ensure that the force generated at the inner location of the heater zone is enough to overcome cohesive forces. The load acting on the accreted ice is a distributed load that increases linearly span-wise. A schematic of the cohesive force opposing the centrifugal force is shown in Figure 10.

317
318
319
320

ManySeveral key parameters must be considered during the design phase of an ice protection system. A flowchart summarizing the design process for a de-icing ice protection system is shown in Figure 11. Utilizing an analytical heat transfer modeling software allowed establishing an initial power density requirement. Based on this requirement, partition zones can be identified. The dimensions of the heater zones must be selected and modeled based on the maximum power availability reserved for the heating system. The heater configuration can be optimized by performing iterations in the modeling phase to find the lowest initial power density. This power density is then used in experimental efforts to find the minimum ice thickness needed for effective shedding, including the effects of zone-to-zone cohesion, for a desired heating time (less than 30 seconds is used in this document).

321
322
323

The testing phase is categorized by “Rotor Environment” and “Power Variation” experiments. To conduct these tests, the testing temperature in the cooling chamber is selected first. Rotor Environment testing begins by matching the droplet impact velocity along the span of the rotor blade. These initial tests identify the ice accretion rate along the span of the rotor blade for various LWC values at representative droplet impact velocities.

324
325

The environment temperature provides knowledge of expected accretion rates for a given icing condition. Temperature and LWC inputs to the controller are used to select the appropriate time sequence to the heaters.

Once representative ice has formed, the centrifugal force acting on the ice shape must match the centrifugal force of the full-scale rotor blade span at each heater zone location. By matching ice loads, these experiments will investigate the boundary of cohesive failure between heater zones. If the ice thickness is too small, the cohesive force of the ice will dominate centrifugal forces, even if the ice-surface interface on the airfoil is melted. Therefore, there exists a minimum centrifugal force required to effectively shed the ice layer from the rotor blade (or ice mass for a given RPM).

During these tests, ice is accreted to a desired thickness. Then the rotor stand spins to the appropriate RPM that matches the full-scale centrifugal load of the inner-zone location of the heater and delivers the selected power density to the heater obtained in the modeling phase. If ice layer sheds in less than the allocated heating time (30 seconds), the next test will decrease the accretion time, which decreases the ice mass. The objective is to find the minimum ice thickness needed for “effective” shedding at each heater zone location. After the minimum thicknesses are found, the 2D cross-sectional area of ice is digitized to obtain the ice mass and calculate the centrifugal force.

The final set of experiments introduce power variation to the heaters. These experiments quantify the time of the shedding events as power density is decreased.

Lastly, the information gathered through this design process produces the capability to design time sequences for each icing condition explored. The time sequences are used by the controller after ice is detected at a given icing condition. As an example of implementation, once ice is detected by ice accretion sensors, a timer begins, and the ice thickness detector will read a thickness after one minute³⁴-(Liu, 2017). The ice accretion rate will determine the icing condition and the appropriate heater sequence is activated. Details on the steps taken to design the heater controller sequence are described in detail in the next sections.

V. De-Icing IPS Experiments

A. Linear Ice Accretion Thickness

The objective of these tests was to find the ice accretion rate (slope of ice thickness over time) along the span of the rotor blade at three different icing conditions. Data from these experiments play a role in the design of the de-icing time sequence controller. A Light icing condition was triggered by a 0.2 g/m³ LWC and 20 μm MVD at a temperature of -8°C. A Medium icing condition consisted of a 0.4 g/m³ LWC and 20 μm MVD at -8°C. Lastly, 0.9 g/m³ and 35 μm MVD combination was selected for the Severe icing condition. The free-stream velocity of the rotor section is summarized in Table 1. The nomenclature for the icing conditions are used throughout the de-icing experiments and results.

It must be noted that the tapering and twist of production blades was ignored on this research. In an effort to develop a design procedure to design electrothermal ice protection systems for wind turbines, twist, blade AOA, and taper variables were ignored.

The RPM used in AERTS during ice accretion must represent the water droplet impact velocity on the wind turbine. For this study, convective cooling plays a major role in the initial stages of ice accretion. The RPM correlation in AERTS that represents the impact velocity at a chosen span percentage of a wind turbine was therefore calculated. After spinning up to the appropriate RPM, the icing cloud was turned on for three different durations: 3, 5 and 7 minutes. The three icing durations would experience the light, medium and severe icing conditions. The key parameters for this set of experiments is shown in Table 1.

Table 1: Linear ice accretion test matrix.

Span %	Impact Velocity (m/s)	AERTS RPM	Accretion Time (mins)
26.7	22.65	174	3, 5 and 7
44.4	37.66	289	3, 5 and 7
62.2	52.76	405	3, 5 and 7
80.0	67.86	521	3, 5 and 7

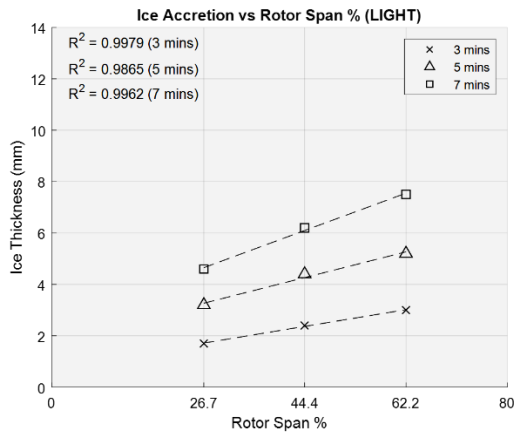

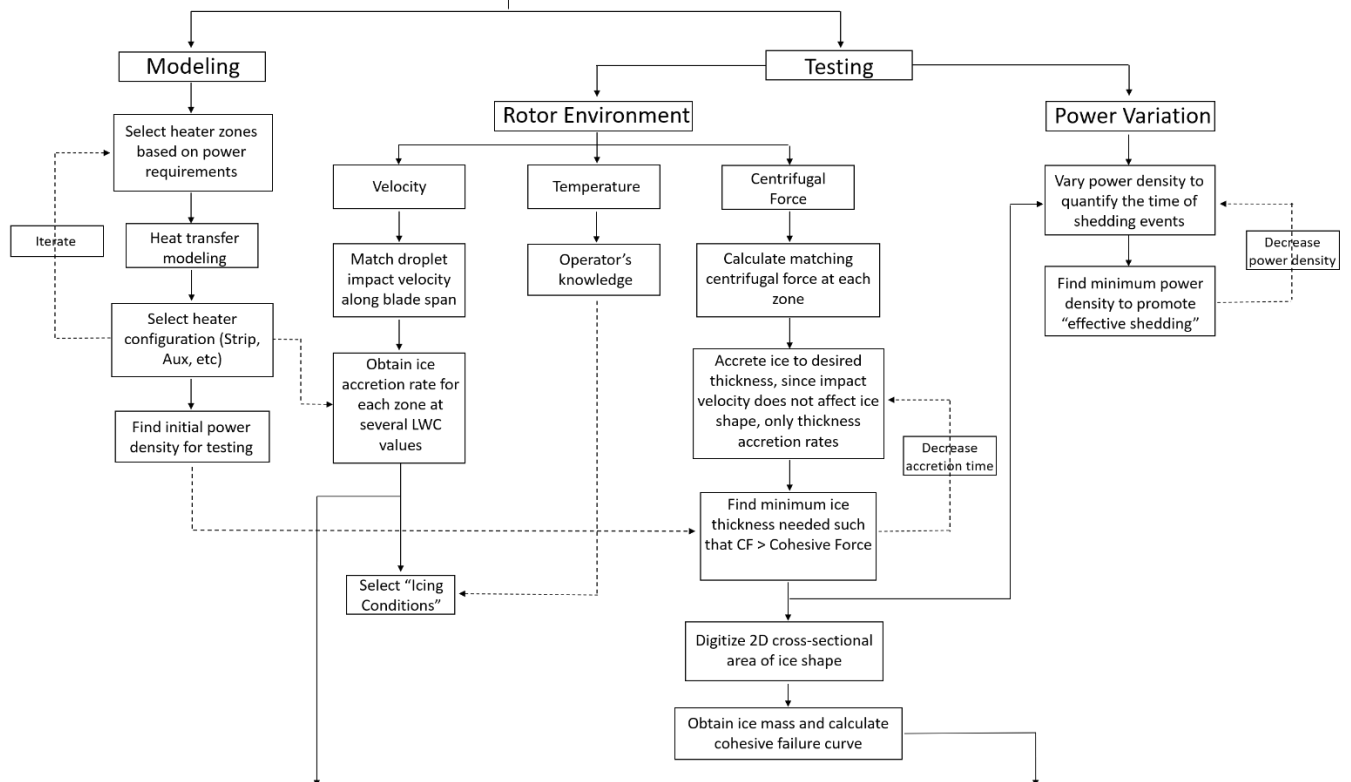

Unfortunately, 80% span was not tested in the AERTS facility due to the potential rotor imbalance on the test stand at such RPM. At 67.86 m/s tip speeds (521 RPM), both blades would need to shed simultaneously, or the force imbalance would become too large for the rotor stand. Note the impact velocity is linear with RPM, while the centrifugal loads are square of the RPM. Therefore, once the desired ice shape was accreted, the RPM was reduced to match centrifugal loads of the full-scale span location.

The data produced from this research, as expected, for the idealized blade conditions (0 AOA, no twist, not taper), found a linear ice accretion along the span of the rotor blade. If the onset of the ice accretion is known, then the accretion rate delivers the capability to know the thickness at each span-wise heater location at any future time. The ice thickness at span percentages outside of the range, 26.7% to 62.2%, can be extrapolated from the data trend. The ice accretion for 3, 5 and 7 minutes at *light* icing conditions is shown in Figure 12. The ice thickness for *medium* and *severe* icing conditions are presented in Figures 13 and 14, respectively. The experimental measurements are used to obtain the ice accretion rate at each zone location.

The data has strong positive correlation and demonstrates a linear behavior for ice thickness along the span of the rotor blade. The experimental measurements can now be used to obtain the ice accretion rate at each zone location.

Ice detection hardwareIn practice, an ice detection system would be required to identify the initial presence of ice on the rotor blades. After a selected time period, the ice detection sensor can measure the ice thickness and the controller interface can calculate the ice accretion rate³⁴-(Liu, 2017). This ice accretion rate determines the severity of the icing conditions and activates the appropriate heater sequence. The accretion rates for each zone in all the icing conditions is presented in Table 2. Interpolation between these icing conditions is possible.

De-Icing System Design

Develop time sequences for the controller based on accretion rates, cohesive failure and required power density for effective shedding

Figure 13: Ice thickness measurements for Medium icing conditions.

Figure 14: Ice thickness measurements for Severe icing condition.

Table 2: Ice accretion rates (mm/min) for each heater zone.

Heater #	Span %	Accretion Rate (LIGHT)	Accretion Rate (MEDIUM)	Accretion Rate (SEVERE)
14	26.7	1.350 mm/min	1.450 mm/min	1.850 mm/min
23	44.4	1.125 mm/min	1.175 mm/min	1.575 mm/min
32	62.2	0.950 mm/min	0.975 mm/min	1.375 mm/min
41	80.0	0.725 mm/min	0.775 mm/min	1.125 mm/min

B. Minimum Ice Thickness for Shedding

It is critical that the ice mass sheds in a timely manner before it becomes a hazard to the infrastructure of the wind turbine or the surroundings. Also, the allowed accreted ice mass must not produce high aerodynamic performance degradation. The following test cases identify the minimum ice thicknesses needed to promote ice shedding at each heater section. The span percentage at the origin of each heater section was selected to calculate the effective centrifugal force acting on the accreted ice. Cohesive bridging was investigated as the ice mass decreased. For shedding to occur, once the ice has debonded from the surface due to heating, the adhesion strength of the ice bridging surface between zones must be less than the centrifugal force pulling on the ice mass in the span-wise direction. If the ice mass is too small, the tensile adhesion strength will dominate over the centrifugal force, creating the inability to shed ice as it will remain attached to the most inner ice section that has not been debonded. Table 3 presents the parameters for these experiments.

Table 3: Properties for Minimum Ice Thickness Shedding experiments.

Heater #	Span %	Shedding RPM in AERTS	Heater Power Density (W/cm ²)	Droplet Impact Velocity (m/s)
14	26.7	286	0.385	52
23	44.4	369		
32	62.2	437		
41	80.0	496		

Each test case accreted ice at -8°C and an impact velocity of 52 m/s (400 RPM in AERTS), deeming the ice accretion rate constant through each icing condition. The impact velocity mostly affects the ice shape and has small effects on the heat transfer once ice is accreted (ice acts as an insulator). The increase of velocity for inner sections with respect to what is expected on a full-scale blade (26.7% and 44.4%) simply means that the accretion rate was increased (since the ice accumulation parameter is linearly dependent on LWC and $\text{time}^{35,36}$ (Anderson, 1994 and Rocco, 2016), and does not have any effects on the capability of the heaters to melt the ice interface. It must be noted that the ice shape could deviate slightly from those accreted at representative span velocities, but ultimately, only the ice mass is of importance for this study. After the test blade accreted an ice shape for a predetermined time, a hot plate was used to remove the tip ice shapes of the paddle blade to create a smooth plane on the edge. Photographs of the cross-sectional area of the ice shape were obtained. After the photograph was taken, the ice on the outer edge of the heater at the tip was removed to ensure the ice mass was free to shed. This represented the outboard heater section on the full-scale turbine that was free of ice. This step had to be done due to the lack of heat production above the outer copper bus bar in the heating element. The copper bus bars, lacking heat generation, were embedded in the heater layer and reside on the inner and outer edge of the heater section. Therefore, the inner section of the heater represented the adjacent inboard heater section on the full-scale wind turbine that has no heat generation. This procedure was repeated for the *light, medium and severe* icing conditions. Figure 15 is a front-view schematic that illustrates the cohesive attachment of the inboard section representative of the full-scale turbine. This procedure experimentally evaluated the cohesive forces of the ice bridging the heater sections. Figures 16 and 17 show the procedure for ice removal on the outer edge of the heater section representing the outboard heater section free of ice on the full-scale turbine.

Figure 15: Schematic of representative inboard heater section with no heat.

Figure 16: Heater section with 4 mm ice accretion before ice removal.

Figure 17: Photograph of the ice removal procedure.

After the rotor test blade is prepared for shedding, the rotor stand spun up to the appropriate centrifugal force representative of the full-scale blade span percentage of interest. When the rotor stand reaches the desired RPM, the heaters were activated and delivered a 0.385 W/cm^2 power density, which is the maximum available due to power restrictions on the full-scale wind turbine (corresponding to 100 kW and a partition of 4 zones per blade). The time limit for effective ice shedding was set to 30 seconds. If the ice mass shed within 30 seconds, the following test case will accrete ice for a shorter duration of time, decreasing the thickness/mass of the ice. This process was conducted until the minimum ice thickness was found for each heater section. After the test was completed and the data was saved, the rotor blades were cleaned in preparation for the next test with reduced ice mass. An example of a 7 mm ice shape at -8°C obtained in the medium icing conditions prepared for shedding is shown in Figure 18. Figure 19 is a photograph of a successful shedding event after 23 seconds for the 26.7% span heater zone (innermost heater zone on the full-scale wind turbine). The data trends for these tests are presented in Figure 20.

490

The minimum ice thicknesses experimentally determined for the *light* icing conditions at the 26.7%, 44.4% and 62.2% span were 6 mm, 4 mm and 2.8 mm, respectively. The average shedding time between both rotor-blades for these tests were 24, 25 and 28 seconds. For the *medium* icing conditions, the minimum ice thicknesses were 3.76.8 mm, 5 mm and 6.83.7 mm, respectively. The average shedding time for these cases were 25, 25 and 23 seconds. Lastly, the minimum ice thicknesses for the *severe* icing conditions were 47.2 mm, 5 mm and 7.24 mm, respectively. The ice shedding times for these tests were 30, 24 and 20 seconds.

Figure 20: Minimum ice thicknesses needed for effective shedding.

491
492

493
494
495
496
497

The minimum thicknesses along the span of the wind turbine blade for the *severe* icing conditions should be considered for the design of the controller. This is a conservative approach, because the smallest variation of ice mass could allow the ice tensile adhesion strength to dominate over the centrifugal forces. In this situation, the ice shape stays attached to the airfoil as the electro-thermal heaters melt the ice interface on the surface. The ice becomes an insulator and continues to accrete ice on the leading edge. It is imperious to keep these ice thicknesses at a minimum for the safety of the surrounding environment on the wind farms.

Side View (From Tip)

498

Figure 21: Schematic of melted interface experience from cohesive bonding.

500 This cohesive “holding” event of a debonded ice zone happened multiple times during the experiments. The following photographs are from a
 501 test case demonstrating the failure to shed and the success of the ice tensile adhesion strength over the centrifugal forces. A side-view schematic from
 502 the tip of the melted interface experienced from cohesive bonding is shown in Figure 21. The melted interface after delivering a 0.385 W/cm^2 power
 503 density from the heaters for 180 seconds and failing to shed is shown in Figure 22. This is an example of the ice mass not reaching the critical value to
 504 successful produce cohesive failure. As stated earlier, on the inboard section of the heater zone, there is a lack of heat generation on purpose to simulate
 505 the cohesive forces in the testing environment. This represents full-scale bridging effects from zone to zone in the field.

506
507

Figure 22: Melted interface between ice and airfoil leading to cohesive bonding and failure to shed.

508 The minimum ice thicknesses along the span for the severe icing condition were used to determine the cohesive failure curve. The cross-
 509 sectional area of the ice shape was photographed and digitized to obtain the 2D area, as stated earlier. The ice mass was used to calculate the centrifugal
 510 force at each heater span location. This data curve represents the minimum centrifugal force needed to exceed the ice cohesive force. If the ice thickness
 511 (mass) exceeds the boundary, centrifugal forces will dominate the cohesive forces. The boundary curve is presented in Figure 23.

512
513

Figure 23: Cohesive failure curve.

514 C. Power Density Variation

515 The last set of experimental tests was conducted to determine the minimum power density needed to debond the accreted ice within the allocated
 516 heating time. Variations of power density delivered to the electro-thermal heater zones was investigated. These experiments were performed for the
 517 minimum thickness needed to prevent cohesion between icing zones and was analyzed for each span-wise heater zone. The objective was to quantify
 518 the required shedding times for reduced power densities at the found minimum ice thickness. As stated in the previous section, effective ice shedding
 519 means the shedding event occurred within 30 seconds. Each test case accreted ice at a water droplet impact velocity of 52 m/s, which corresponds to

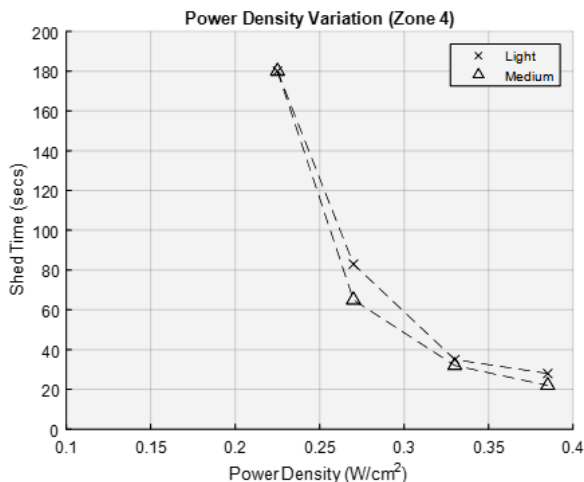

400 RPM in the AERTS facility. After the minimum thickness was accreted, the icing cloud was turned off and the rotor stand spun down. The same ice removal technique as stated earlier was conducted to eliminate the last inch of ice from the tip, span-wise (region over the bus bar used to power the heater). The rotor stand spun up to the desired RPM that corresponded to the centrifugal force at the heater zone being tested. When the matching centrifugal force was achieved, power was delivered to the electro-thermal heaters at a selected power density. The maximum available power density given the maximum power available for the heating system (100 kW), 0.385 W/cm² was the initial value before decreasing power density for the latter test cases. The ice shedding times were quantified and recorded for the *Light* and *Medium* icing conditions. Once again, the *Light* icing condition pertains to a 0.2 g/m³ LWC and 20 μm MVD at a -8°C temperature. The *Medium* icing conditions are a 0.4 g/m³ LWC and 20 μm MVD at a -8°C temperature. The parameters of the test matrix for the power variation experiments are shown in Table 4.

528

Table 4: Test matrix for de-icing IPS power variation.

Heater #	Span %	Heater Power Density (W/cm ²)	Shedding RPM in AERTS	Icing Condition
4	26.7	0.385, 0.33, 0.27, 0.225	286	LIGHT & MEDIUM
3	44.4	0.385, 0.33, 0.27, 0.225	369	LIGHT & MEDIUM
2	62.2	0.385, 0.33, 0.27, 0.225	437	LIGHT & MEDIUM

529 The test cases for the innermost heater zone, Heater 4, accreted an average of 6 mm of ice on the leading edge in *Light* icing conditions. For the
 530 0.385, 0.33, 0.27 and 0.225 W/cm² power densities, the average shedding times were 28, 35, 83 and >180 seconds, respectively. The test cases for
 531 Heater 4 on average accreted a 7 mm ice thickness on the leading edge in *Medium* icing conditions. For the 0.385, 0.33, 0.27 and 0.225 W/cm² power
 532 densities, the average shedding times were 22, 42, 65 and >180 seconds, respectively. The data trend for the innermost heating section, zone 4, is shown
 533 in Figure 24.

534

535

Figure 24: Power density variation shedding times for heater zone 4.

536 The test cases for heater zone 3 accreted an average ice thickness of 4 mm on the leading edge in *Light* icing conditions. For the 0.385, 0.33,
 537 0.27 and 0.225 W/cm² power densities, the average shedding times were 25, 48, 88 and >180 seconds, respectively. Test cases in the *Medium* icing
 538 conditions accumulated an average ice thickness of 5 mm. For the 0.385, 0.33, 0.27 and 0.225 W/cm² power densities, the average shedding times were
 539 25, 38, 82 and >180 seconds, respectively. The data trend for heater zone 3 is shown in Figure 25.

Figure 25: Power density variation shedding times for heater zone 3.

Lastly, heater zone 2 accreted 3 mm of ice on the leading edge for *Light* icing conditions. For the 0.385, 0.33, 0.27 and 0.225 W/cm² power densities, the average shedding times were 28, 47, 67 and >180 seconds, respectively. Test cases in the *Medium* icing conditions accreted an average ice thickness of 3.7 mm. For the 0.385, 0.33, 0.27 and 0.225 W/cm² power densities, the average shedding times were 24, 57, 85 and >180 seconds, respectively. The power variation data trend is presented in Figure 26.

Figure 26: Power density variation shedding times for heater zone 2.

The data shows a parabolic trend indicating that the variation of power density plays a critical role in the heat transfer physics. Small changes in power density can result in shedding times above the “effective shedding” requirement. Therefore, the maximum power available on the 1.5 MW wind turbine established for the parametric design is needed for the de-icing ice protection system to perform in varying icing conditions given the heating zones selected.

VI. Controller Design

The controller is dependent upon the ice accretion rates, found in Table 2, and the minimum ice thickness required for effective shedding. A crucial hardware for the integration of the system is an ice detection sensor. It was not the aim of this research to explore the capabilities of suitable ice detection sensors. The controller interface needs to know when ice is initially present and the ice thickness after a selected time period. These two steps are needed for identifying the icing condition, since the ice accretion rate determines the icing condition experienced. Each icing condition has a repeatable time sequence operation to de-ice the rotor blades and minimize aerodynamic penalties. The time sequence incorporates the minimum ice thickness needed to ensure the ice accretion reaches that critical value to overcome cohesive forces. The controller time sequences for *Light*, *Medium* and *Severe* icing conditions are presented in Figures 27-29, respectively. The controller operations are illustrated as a flowchart in Figure 30.

Figure 27: Repeatable time sequence for *Light* icing conditions.

Figure 28: Repeatable time sequence for *Medium* icing conditions.

The horizontal lines represent the minimum ice thicknesses for each heater zone needed to produce cohesive failure. The slope of each line represents the ice accretion rate (mm/second) found experimentally at each zone. When the ice thickness for each zone exceeds the critical thickness value, the centrifugal force on the ice mass will dominate the ice cohesion force with the adjacent heater zone. The downward slope after the peak for each zone represents the effective shedding requirement of 30 seconds.

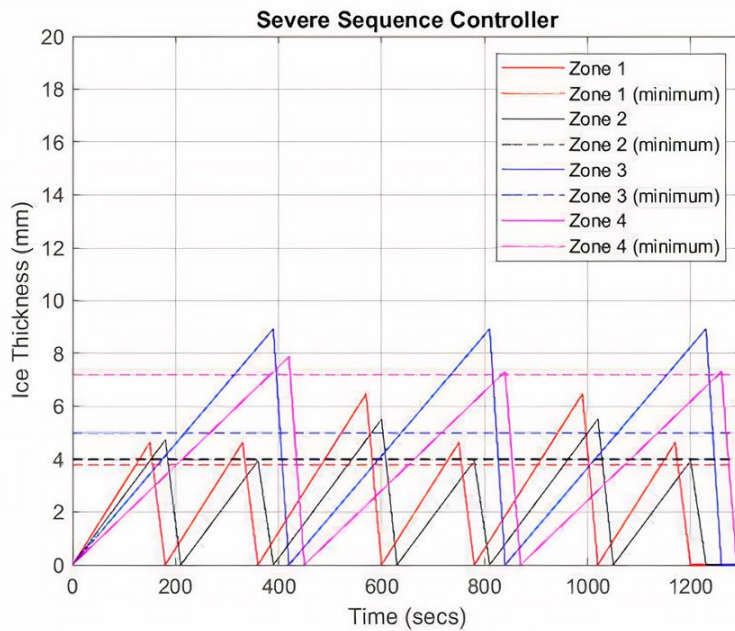

Figure 29: Repeatable time sequence for Severe icing conditions.

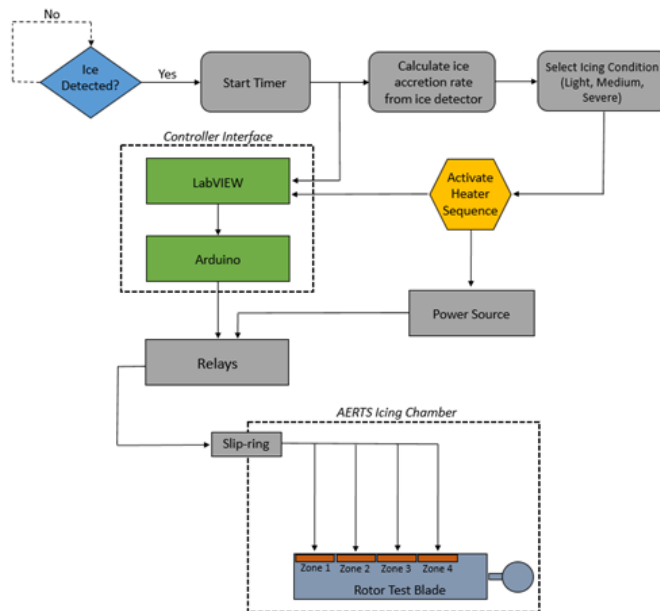

572
573

574
575
576

The most inboard zone, heater 4, has the smallest accretion rate and the longest time duration to reach the critical thickness value. Heater zone 3 must sacrifice aerodynamic performance to allocate the proper time to produce a shedding event for zone 4, because zone 3 must shed prior and be ice-free before zone 4 is activated.

577
578
579
580

Knowing ice thickness rates ensures that the controller does not attempt to de-ice when the ice thickness has not reached a critical ice thickness. If ice sensors are not available, a conservative approach could be to turn on the heaters for a time sequence corresponding to the Light icing condition, which allows more time for ice to accrete. Such approach would introduce aerodynamic penalties for the Medium and Severe icing conditions, as the ice thickness accreted will exceed the minimum thickness required for shedding.

581

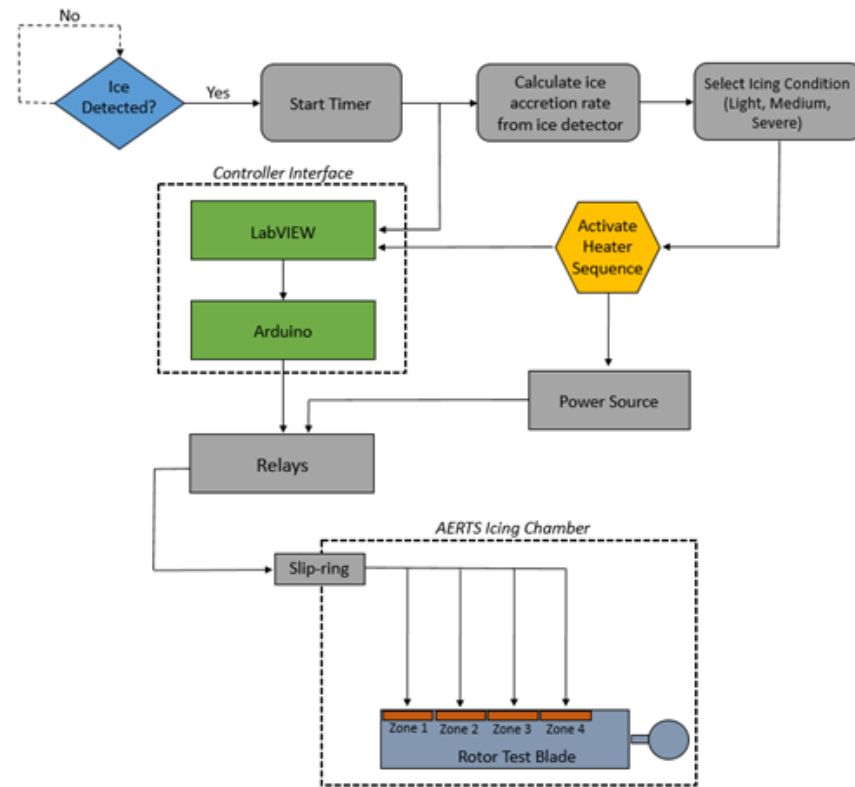

Figure 30: Flowchart of controller operations.

VII. Conclusions / Future Work

The wind turbine industry is rapidly expanding and there is a need for an effective and low-power ice protection system. An electro-thermal heater system ~~was designed and tested~~ design procedure for a representative 1.5 MW wind turbine. ~~Experimental work was conducted~~ is described. The procedure relies on experimental data to:

1. Obtain the ice accretion slope along the span of the wind turbine blade utilizing the DU 93-W-210 airfoils for representative icing conditions.
2. Determine the minimum thickness needed to effectively shed ice without cohesive bonding between heater zones, while delivering a 0.385 W/cm^2 power density to the electro-thermal heaters (maximum power density available on the turbine for the ice protection system).
3. Explore the time variation of ice shedding by decreasing the power density to the electro-thermal heater to attempt to lower power delivery to the zones.
4. Design a time sequence controller based on ice accretion rates for varying icing conditions to minimize ice accretion mass and aerodynamic penalties.

The ice accretion rates for the selected icing conditions ranged from 0.725 mm/min to 1.850 mm/min . Light icing conditions were created using clouds at -8°C with a 0.2 g/m^3 liquid water content (LWC) and water droplets of $20 \mu\text{m}$ median volumetric diameter (MVD). Medium icing condition clouds had a LWC of 0.4 g/m^3 and $20 \mu\text{m}$ MVD, also at -8°C . Severe icing conditions had an LWC of 0.9 g/m^3 and $35 \mu\text{m}$ MVD at -8°C . The minimum thicknesses for each heater zone beginning with the outboard section were 3.8 mm , 4.0 mm , 5.0 mm and 7.2 mm . These values were obtained experimentally and represent the full-scale ice debonding of a heating zone, which overcomes cohesive bonding of adjacent ice regions. The accreted ice thickness must reach these values at each heater zone to ensure the centrifugal force overcomes the ice cohesion force between zones. For the design of the controller, an effective shedding time limit was imposed. With a 0.385 W/cm^2 heater power density, each zone was required to shed the minimum ice thickness within 30 seconds. The power density was then varied to lower values to measure the time discrepancy between shedding events. It was found that lower power densities are not suitable for the proposed configuration.

Accreting a certain required thickness of ice to eliminate cohesive bonding, but also keeping the ice mass that shed to a minimum for the surrounding safety, aerodynamic degradation minimization/reduction, and reduction of potential imbalance forces is critical. Understanding what type of weather conditions that the wind turbine experiences at its location throughout the annual season is imperative, specifically, knowing the ice accretion rate at a given icing condition. Current modeling tools provide a starting point to design such de-icing systems, but given the uncertainties of ice accretion to wind turbines, variations on heater performance, and blade manufacturing schemes (affecting heat transfer), experimental testing procedures are suggested in this paper for the design of de-icing systems for wind turbines. Future experiments should incorporate a test rig with multiple heater zones to effectively test for a full system performance, including integration of an ice detection sensor.

The research was successful groundwork for the design of a de-icing ice protection system. Using ice thickness measurements allows for the design of a time sequence algorithm for varying icing conditions and minimizing ice accretion mass. If the ice accretion rate per time is known, the type of icing condition can be approximated, and that appropriate heater sequence timing can be interpolated.

VIII. Acknowledgments

The work explored was funded by DuPont under a contract with The Pennsylvania State University Aerospace Department. ~~The research was directed with the advice and expertise of Professor, Dr. Jose Palacios. The collaboration between the teams was an amazing experience and undoubtedly the reason for great results in this research.~~ The authors would like to thank Matthew Manelis and Clinton Miley from Dupont for the collaboration during this rewarding research effort.
