Abstract. Due to financial and temporal limitations, the small wind community relies upon simplified wind speed models and energy production simulation tools to assess site suitability and produce energy generation expectations. While efficient and user-friendly, these models and tools are subject to errors that have been insufficiently quantified at small wind turbine heights. This study leverages observations from meteorological towers and sodars across the United States to validate wind speed estimates from the Wind Integration National Dataset (WIND) Toolkit, the European Centre for Medium-Range Weather Forecasts (ECMWF) Reanalysis v5 (ERA5), and the Modern-Era Retrospective Analysis for Research and Applications, version 2 (MERRA-2), revealing average biases within ±0.5 m s⁻¹ at small wind hub heights. Observations from small wind turbines across the United States provide references for validating energy production estimates from the System Advisor Model (SAM), Wind Report, and MyWindTurbine.com, which are seen to overestimate actual annual capacity factors by 2.5, 4.2, and 11.5 percentage points, respectively. In addition to quantifying the error metrics, this paper identifies sources of model and tool discrepancies, noting that interannual fluctuation in the wind resource, wind speed class, and loss assumptions produce more variability in estimates than different horizontal and vertical interpolation techniques. The results of this study provide small wind installers and owners with information about these challenges to consider when making performance estimates and thus possible adjustments accordingly. Looking to the future, recognizing these error metrics and sources of discrepancies provides model and tool researchers and developers with opportunities for product improvement that could positively impact small wind customer confidence and the ability to finance small wind projects.

1 Introduction

The total global installed capacity of small wind turbines is estimated at approximately 1.8 GW (Orrell et al., 2021). In the United States, small wind turbines (i.e., wind turbines with rated capacities of 100 kW or less) comprise a national installed capacity of more than 150 MW and are poised for continuing contribution to the role distributed energy resources play in the decarbonization of the U.S. economy (Orrell et al., 2021). In addition to helping to reach decarbonization goals, small wind turbines, standalone or as components of hybrid power systems, have the potential to improve energy accessibility, equity, and security for rural and underrepresented communities. Bednar and Reames (2020) report stark disparities in the percentage of household income spent on energy bills across the U.S., with disproportionately high energy burdens falling on low-income, African American, Latinx, and multifamily households. Fathollahzadeh et al. (2021) note that Native American nations are approximately 10 times more likely to lack access to primary services, such as electricity, than the average U.S. household. To address this disparity, Fathollahzadeh et al. (2021) propose a methodology to establish electricity demand, simulate wind and solar contributions in a hybrid system, and select an ideal hybrid system installation location.

Consumer adoption of small wind is influenced by multiple factors, including project costs, availability of incentives, and confidence in the turbine’s ability to generate energy. The last of these factors is strongly affected by the level of accuracy in the prediction of energy production at a site of development interest (Fields et al., 2016; Acker et al., 2019). Accurate energy production estimates begin with an understanding of the available wind resource. While large-scale wind plants have the means to perform detailed observation-driven wind resource and site assessments, small-scale wind projects typically rely on models and assessment tools to survey the energy production potential at a location of interest (Drew et al., 2015). In this study, we evaluate the performance of wind resource assessments at small wind hub heights (10 m to 50 m) based on three models and reanalyses available to the small wind industry: the Wind Integration National Dataset (WIND) Toolkit developed by the National Renewable Energy Laboratory (Draxl et al., 2015a), the European Centre for Medium-Range Weather Forecasts (ECMWF) Reanalysis v5 (ERA5) (Hersbach et al., 2020), and the National Aeronautics and Space Administration (NASA) Global Modeling and Assimilation Office (GMAO) Modern-Era Retrospective Analysis for Research and Applications, version 2 (MERRA-2) (Gelaro et al., 2017).

Validations of models that provide wind resource simulations are plentiful but tend to focus on heights near the surface (10 m or less) (Carvalho, 2019; Wang et al., 2019; Gruber et al., 2019; Molina et al., 2021) or are relevant to utility-scale and offshore wind hub heights, typically 50 m and higher (Draxl et al., 2015b; Olason, 2018; Gruber et al., 2019; Jourdier, 2020; Brune et al., 2021). Typical small wind turbine hub heights range between 10 m and 50 m (Orrell et al., 2018, 2021), and model wind speed validations at these heights exist in more limited quantities. Ramon et al. (2019) validated reanalysis-based wind speeds using 77 global meteorological towers with measurement heights ranging from 18 m to 122 m. They found median seasonal biases between 0 m s⁻¹ and -1 m s⁻¹ and correlation coefficients around 0.8 for ERA5 and MERRA-2, however error metrics according to height above ground were not specified. Kalverla et al. (2020) analyzed measurements ranging from 27 m to 315 m over the North Sea and determined that ERA5 underestimates the observed wind speed by ~0.5 m s⁻¹ across the
vertical wind speed profile. For three sites in California with wind speed measurements at 30 m, Hodge (2016) determined seasonal and diurnal correlation coefficients for the WIND Toolkit ranging from 0.40 to 0.96. At locations in Colorado and Washington, Poudel et al. (2019) found WIND Toolkit wind speed biases at small wind hub heights of -1.1 m s\(^{-1}\) and -0.63 m s\(^{-1}\), respectively. In Arizona, Acker et al. (2019) found the WIND Toolkit to be a satisfactory wind speed data product for simulating annual energy production within a computational flow modeling framework. This work aims to provide a more complete understanding of simulated wind speed performance at small wind hub heights in order to highlight areas of improvement for model developers and to educate small wind adopters on the limitations of the modelled data.

Our analysis continues with an evaluation of three energy production simulation tools: the System Advisor Model (SAM) from the National Renewable Energy Laboratory (NREL) (2021a), Wind Report from Bergey WindPower Co. (2021), and MyWindTurbine.com from the Technical University of Denmark (DTU) Wind Energy research organization and Energi- og MiljøData (EMD) International A/S (2021). These user-friendly and budget-friendly tools combine wind resource models, such as the WIND Toolkit, with power curve databases and loss assumptions to produce site-specific annual energy production estimates. While validations of SAM exist for solar technology using actual plant performance data (Freeman et al., 2013; Rudié et al., 2014; Ezeanya et al., 2018; Freeman et al., 2019), we were unable to determine similar validations of SAM for small wind systems. Similarly, no validation of Wind Report using turbine production observations was able to be identified. Bechmann et al. (2016) provide a performance evaluation of MyWindTurbine.com using 20 small wind turbines in Denmark, but note that the wind resource datasets specific to Denmark employed by MyWindTurbine.com are different and presumably better than the datasets used for the rest of the world and recommend more expansive validation efforts. This study will provide validations for all three tools across the United States using actual small wind turbine performance data so that small wind adopters are made aware of the uncertainties associated with each tool and can make adjustments to output expectations accordingly.

The remainder of this paper is organized as follows: In Sect. 2, the wind speed and energy production observations, models, and tools considered in the study are described. Sect. 2 concludes with a discussion on the error metrics employed to validate each model and tool. Sect. 3 presents the findings of the validation, beginning with the overall model wind speed performance metrics and continuing into a discussion of these results according to the diurnal cycle and observed wind speed class. Sect. 3 proceeds with the energy production validation and explores these results according to geographic region, turbine type, and hub height. Sect. 3 concludes with an investigation into the sources of discrepancy between actual and simulated small wind turbine production, quantifying the potential impact of each identified source on the accuracy of the simulations. Finally, Sect. 4 summarizes the results of Sect. 3 into a comprehensive guide to understanding the uncertainty in wind resource and energy production estimates for small wind turbines, provides recommendations for application of the findings to real world small wind turbine resource assessments, and concludes with an outlook into new and upcoming advancements in simulation technology that will benefit the small wind community.
2 Data Discussion and Methodology

2.1 Wind Speed Observations

The observational wind speed datasets for this study are drawn from U.S. Department of Energy National Laboratories (Argonne National Laboratory, Brookhaven National Laboratory, NREL, Oak Ridge National Laboratory, Pacific Northwest National Laboratory, Savannah River National Laboratory), the National Oceanic and Atmospheric Administration (National Centers for Environmental Information, National Data Buoy Center), the Bonneville Power Administration, the University of Massachusetts, and the first Wind Forecast Improvement Project (Wilczak et al., 2015). These in situ measurements were gathered from anemometers on meteorological towers or collected using sodars. Taken together, this data collection combines publicly available data (46 sites), data available upon request (1 site), and data subject to non-disclosure agreements (15 sites) as outlined in the data availability statement.

![Figure 1](https://example.com/figure1.png)

**Figure 1.** (a) Number of locations and annual average observed wind speeds determined from the measurements made in each state (states with insufficient observations at small wind heights are indicated in grey) and (b) histogram of wind speed observations according to measurement height.

The 62 resulting observations are diverse in geography and terrain complexity, spanning 27 states (Fig. 1a), and height above ground (Fig. 1b). Several observations on islands are included because small wind turbines play a role in mitigating electrical power generation costs in remote and isolated communities (Devine et al., 2004; Dilley and Hulse, 2007; Kolbert, 2008). To ensure a high-fidelity reference dataset for validation, the wind speed observations are quality-controlled via the removal of instances or periods of atypical or unphysical reported wind speeds (less than 0 m s\(^{-1}\), greater than 50 m s\(^{-1}\), or...
nonvarying values over periods of time greater than three hours). In order to maintain representation of the seasonal cycle and consistent standards for comparison of error metrics on a site-by-site basis, wind speed observations with 80% of greater data recovery for each complete year of the data record are included. The temporal coverage of the wind speed observations ranges from one to seven years, with an average of four years. For the 48 observations that cover two years or more, the interannual standard deviations of annual average wind speeds range from 0.01 m s\(^{-1}\) to 1.25 m s\(^{-1}\) with an average standard deviation of 0.24 m s\(^{-1}\). The maximum interannual differences between annual average wind speeds range from 0.02 m s\(^{-1}\) to 3.33 m s\(^{-1}\) with an average maximum difference of 0.58 m s\(^{-1}\).

2.2 Wind Resource Models

Wind resource estimates from three commonly used models or reanalysis products are evaluated in this study and described in Table 1. The WIND Toolkit is specifically designed to support wind integration studies (Draxl et al., 2015a), while ERA5 (Hersbach et al., 2020) and MERRA-2 (Gelaro et al., 2017) are reanalysis products that provide a broad spectrum of atmospheric variables, including wind information, and are commonly employed in wind energy studies (Olauson, 2018; Rabbani and Zeeshan, 2020; Pryor and Barthelmie, 2021; Samal, 2021). While the WIND Toolkit covers a shorter period of time than the reanalyses and does not include data assimilation, it provides better spatial and temporal resolution (Table 1).

</tbody>
</table>

\(^a\)The data have been converted from the native reduced Gaussian grid to a regular latitude-longitude grid at 0.25° (Hersbach et al., 2020).

For each of the gridded model datasets in Table 1, two horizontal interpolation techniques are considered in the validation analysis: nearest neighbor (selecting the closest geographical grid point to the observational location) and distance-weighted (triangulation-based linear interpolation to the observational location using the four surrounding grid points). Vertically, if an observational height is identical to a model output height, the wind speed at that model output height is employed in the validation with no adjustment. Because each model in Table 1 outputs wind speed information at or above and below each
height in the observational wind speed collection, the power law shown in Eq. (1), in conjunction with a dynamic shear exponent ($\alpha$), as shown in Eq. (2), calculated using the simulated wind speeds $v_{lo}$ and $v_{hi}$ from the two surrounding model heights $z_{lo}$ and $z_{hi}$, is employed for locations requiring model adjustment to measurement height. This vertical interpolation scheme for simulation of the wind speed at the measurement height is selected because it considers multiple levels in the wind speed profile and does not rely on static stability assumptions (Olauson and Bergkvist, 2015).

$$v = v_{lo} \left( \frac{z}{z_{lo}} \right)^{\alpha}$$

(1)

$$\alpha = \ln \left( \frac{v_{hi}}{v_{lo}} \right) / \ln \left( \frac{z_{hi}}{z_{lo}} \right)$$

(2)

The horizontal and vertical interpolation schemes employed in this validation were evaluated for the WIND Toolkit by Duplyakin et al. (2020) and their resultant error metrics were found to vary minimally according to these and other interpolation schemes. This work builds upon their findings and extends the horizontal interpolation comparison to coarser models, namely ERA5 and MERRA-2, for which the choice of interpolation scheme may yield more significant differences in the resultant simulated wind speeds.

### 2.3 Energy Production Observations

The energy production observations utilized in this validation are from individual small wind turbines courtesy of APRS World, Argonne National Laboratory, Bergey WindPower Co., Claverack Rural Electric Cooperative, Inc., and the New York State Energy Research and Development Authority. Similar to the observational wind speed collection, the energy production observations from 55 turbines are diverse in geography and terrain complexity, spanning 24 states (Fig. 2a), and in turbine hub height (Fig. 2b). Four different turbine models with rated capacities ranging from 8.9 kW to 56 kW are included in the observational collection, as shown in Table 2 with their associated power curves displayed in Fig. 2c.

![Figure 2](https://doi.org/10.5194/wes-2021-111)

Figure 2. (a) Number of locations and annual average capacity factors per state (states with insufficient small wind turbine production observations are indicated in grey), (b) histogram of turbine hub heights, and (c) turbine power curves employed in this study.
To allow for comparisons with simulated annual energy production estimates, complete years of energy production observations are employed in this validation. The temporal coverage of the energy production observations ranges from one to ten years, with an average of five years. The resolution of turbine availability data ranges from no availability data provided to highly detailed availability data, as in the APRS World and Bergey WindPower Co. collection, which provides the percent of time each turbine is running, waiting for wind, and stopped for a variety of reasons. In order to facilitate the comparison of energy production across turbines with different rated capacities, the average annual energy production from each turbine is divided by the product of the unique turbine rated capacity and the number of hours in one year, resulting in a capacity factor percentage. The 55 turbines employed in this validation produced capacity factors ranging from 1.2% at a location in the Southeast, a region characterized by lower wind resource relative to the rest of the United States (NREL, 2021b), to 28.2% at a local elevation maximum in the Northeast.

#### 2.4 Energy Production Tools

Three simple, user-friendly tools for energy production simulation are evaluated to establish a baseline of accuracy of the estimates and to assess the trade-off between tool efficiency and accuracy. SAM, Wind Report, and MyWindTurbine.com provide localized annual energy production estimates in kWh in a matter of seconds to minutes on a standard laptop computer. Each tool is driven by model wind resource information that is either provided by the user or more conveniently included in the tools, as reported in Table 3. By default, SAM employs the WIND Toolkit for wind resource data and Wind Report sources wind resource data from a model with similar spatial resolution. MyWindTurbine.com uses model wind resource data from the Global Wind Atlas 1.0 with a spatial resolution similar to MERRA-2 for countries outside of Denmark. Within Denmark, MyWindTurbine.com utilizes wind climate estimates from Weather Research and Forecasting (WRF) model output (Hahmann et al., 2014). SAM allows a user to select a single year of WIND Toolkit wind resource data for annual energy production estimation, the default of which is 2013.

The three tools allow a user to select a turbine model (power curves provided), hub height, and geographic location to simulate annual energy production. To account for the losses that inevitably occur during the production lifecycle of an actual
turbine, each tool is equipped with customizable loss factors, with the default values shown in Table 3. The Wind Report loss factor is attributed to turbulence, while MyWindTurbine.com separates the loss assumptions into the categories of availability and electrical losses. SAM provides 20 categories of loss assumptions for wind turbines, including wake, availability, electrical, turbine performance, environmental, and curtailment/operational strategies losses.

2.5 Error Metrics and Statistical Significance

The wind speed validation employs three error metrics to assess the accuracy of model representation of observed wind speeds: wind speed bias, mean absolute error, and correlation coefficient. The wind speed bias, i.e., the average difference over a timeseries of length $N$ between the modelled ($v_{mod,i}$) and observed ($v_{obs,i}$) wind speeds, informs a model user whether their model of choice tends to overestimate (positive bias), underestimate (negative bias), or accurately represent (zero bias) the observed wind resource:

$$Bias = \frac{1}{N} \sum_{i=1}^{N} (v_{mod,i} - v_{obs,i})$$

The mean absolute error (MAE) is the absolute difference between the modelled and observed wind speeds, informing a user of the magnitude of error:

$$MAE = \frac{1}{N} \sum_{i=1}^{N} |v_{mod,i} - v_{obs,i}|$$

Finally, the Pearson correlation coefficient informs a model user of the degree to which the modelled and observed wind speeds are linearly related, with values close to one indicating a high degree of correlation:

$$Correlation = \frac{\sum_{i=1}^{N} (v_{mod,i} - \bar{v}_{mod})(v_{obs,i} - \bar{v}_{obs})}{\sqrt{\sum_{i=1}^{N} (v_{mod,i} - \bar{v}_{mod})^2} \sqrt{\sum_{i=1}^{N} (v_{obs,i} - \bar{v}_{obs})^2}}$$
For the energy production validation, we examine the results in terms of capacity factor error, the difference between the simulated and observed capacity factors.

Standard statistical methods are used to determine whether observed differences between the error metrics produced by the wind speed and energy production simulations are statistically significant. Paired-sample t-test and Wilcoxon rank sum tests (Fay and Proschan, 2010) are used for pairwise analysis between models and methods. These tests assess the null hypothesis that the true mean (or median for the Wilcoxon test) of the differences between observations is zero. Significance is determined with an alpha threshold for type 1 error set to 0.05. Hence, we reject the null hypothesis and accept the alternative hypothesis that the differences are significant when the observed p-value is less than 5%, indicating a less than 5% chance the observed differences could be due to random chance. The Bonferroni method is used to account for multiple comparisons while interpreting the results. All statistical analyses are performed with the R software environment for statistical computing version 4.0.

3 Results

3.1 Wind Speed Validation

Across the 62 sites providing wind speed observations, the WIND Toolkit and MERRA-2 produce the smallest absolute biases on average (Fig. 3a). The WIND Toolkit slightly overestimates the observed wind speeds by an average of 0.2 m s\(^{-1}\), regardless of horizontal interpolation technique (nearest neighbor and distance-weighted). MERRA-2 slightly underestimates the observed wind speeds by a similar magnitude and the choice of interpolation technique shows more impact on the results for this coarser product, with biases of -0.2 m s\(^{-1}\) and -0.1 m s\(^{-1}\) for the nearest neighbor and distance-weighted interpolation techniques, respectively. ERA5 also underestimates the observed wind speeds and produces the largest magnitude bias on average across the sites: -0.5 m s\(^{-1}\) regardless of horizontal interpolation technique, a result that aligns with the findings of Kalverla et al. (2020) for winds over the North Sea. Applying the t-test to the bias results reveals that the mean bias is significantly different from zero for ERA5, and not for the WIND Toolkit or MERRA-2. The t- and Wilcoxon tests reveal that for wind speed bias, each model performs significantly differently from one another, while the impact of horizontal interpolation choice within each model is insignificant.

As shown in Fig. 3a, the wind speed models produce bias magnitudes in excess of 3 m s\(^{-1}\) at several sites, each of which are located among complex terrain. For instance, the WIND Toolkit overestimates the observed wind speed by nearly 4 m s\(^{-1}\) at a site in the Colorado Rocky Mountains. ERA5 underestimates the observed wind speed at this location, with a bias of -1.8 m s\(^{-1}\), while MERRA-2 produces very little bias (-0.1 m s\(^{-1}\)). Interestingly, all three models produce consistent and relatively high correlation coefficients between 0.7 and 0.8 at this site. At two sites along the Columbia River Gorge in the Pacific Northwest, ERA5 strongly underestimates the wind resource, with wind speed biases of -4.6 m s\(^{-1}\) and -3.3 m s\(^{-1}\). MERRA-2 also underestimates the wind resource at these sites, with biases of -3.7 m s\(^{-1}\) and -1.9 m s\(^{-1}\). Conversely, the WIND Toolkit produces wind speed biases near zero at these locations.
Figure 3. Wind speed (a) bias, (b) MAE, and (c) correlation across 62 sites as produced by the WIND Toolkit, ERA5, and MERRA-2 using the nearest neighbor (NN) and distance-weighted interpolation (Int) techniques. The median error metrics are indicated with the red lines, the 25th and 75th percentiles form the blue boxed range, the minimum and maximum error metrics, excluding outliers, are in black, and outliers are indicated with red plus signs. The mean error metrics are represented with black stars.

The three wind resource models produce similar values on average for MAE, 1.7 m s\(^{-1}\) from the WIND Toolkit and ERA5 and 1.8 m s\(^{-1}\) from MERRA-2 (Fig. 3b). The t- and Wilcoxon tests do not detect a significant difference between the models for this metric, however limited sample size may contribute to this result. Differences in MAE according to interpolation technique are only significant for MERRA-2, the coarsest product. The same sites in the Colorado Rocky Mountains and the
Columbia River Gorge that produced the largest magnitude biases are also responsible for the MAE outliers greater than 3 m s\(^{-1}\).

Significant differences in correlation between the WIND Toolkit and MERRA-2 are not noted by the t- and Wilcoxon tests, and each model produces an average correlation of 0.74 (Fig. 3c). The correlations produced by ERA5, with an average value of 0.77, are significantly different from the other two models. According to the t- and Wilcoxon tests, choice of interpolation technique is significant for this metric across the models. The smallest correlations (less than 0.5) occur for the coarser resolution models (ERA5 and MERRA-2) in geographically diverse locations that feature complex terrain, namely the Colorado Front Range, the hilly California coast, the Columbia River Gorge, and the Green Mountains in Vermont. The highest correlations (around 0.9) occur at locations on islands or along the coasts of the Atlantic Ocean, Pacific Ocean, Gulf of Mexico, and Great Lakes, where the wind resource tends to be faster than further inland, and in the Upper Midwest.

### 3.1.1 Diurnal Trends in Simulated Wind Speed Performance

Model performance across the diurnal wind speed cycle provides important context for load balancing across standalone small wind systems and as a complement to solar technology. Comparisons between observed and modeled diurnal wind speed cycles exist for the WIND Toolkit (Takle et al., 2017), ERA5 (Jourdier, 2020), and MERRA-2 (Jourdier, 2020) at a variety of heights above the ground. Because the shape of the diurnal wind speed cycle varies according to height above ground (Crawford and Hudson, 1973), among other factors, it is of interest to examine model performance by hour at heights specific to small wind development, as in Fig. 4. The average diurnal patterns of MAE and correlation (Fig. 4b, c) are consistent across the three models, with the lowest MAEs and highest correlations achieved around local noon. The hourly WIND Toolkit bias, however, follows a different trend as compared to ERA5 and MERRA-2 (Fig. 4a). The WIND Toolkit bias reaches the most negative values during the morning hours, while the ERA5 and MERRA-2 biases reach the most negative values during the late afternoon.

![Figure 4](https://doi.org/10.5194/wes-2021-111)

**Figure 4.** Average diurnal wind speed (a) bias, (b), MAE, and (c) correlation across 62 sites at heights ranging from 10 m to 50 m using distance-weighted horizontal interpolation.
3.1.2 Simulated Wind Speed Performance According to Wind Speed Class

The simulated wind speed biases trend increasingly negative with increasing observed wind, as presented in Fig. 5. At the slowest wind speeds, from 0 m s\(^{-1}\) to 5 m s\(^{-1}\), the WIND Toolkit, ERA5, and MERRA-2 tend to overestimate the observed wind speed by 0.9 m s\(^{-1}\), 0.4 m s\(^{-1}\), and 0.8 m s\(^{-1}\), respectively. This result informs a user that converting the model wind speeds to power may result in inflated energy production expectations, as there may be instances of the model wind speeds exceeding turbine cut-in while the observed wind speeds are actually below cut-in. As the observed wind speeds increase, the biases exhibited by each model become more negative, with the WIND Toolkit, ERA5, and MERRA-2 producing biases of \(-5.2\) m s\(^{-1}\), \(-7.2\) m s\(^{-1}\), and \(-6.7\) m s\(^{-1}\), respectively, for observed wind speeds greater than 20 m s\(^{-1}\). Conversely to the slow wind speed assessment, this result warns a user that high wind speed turbine cut-out events may occur more frequently than the models indicate. With the exception of the slowest wind speed class, from 0 m s\(^{-1}\) to 5 m s\(^{-1}\), the ERA5 and MERRA-2 biases are not significantly different.

![Figure 5](https://doi.org/10.5194/wes-2021-111)

**Figure 5.** Distance-weighted model wind speed bias according to observed wind speed class. The median biases are indicated with the red lines, the 25th and 75th percentiles form the blue boxed range, the minimum and maximum error metrics, excluding outliers, are in black, and outliers are indicated with red plus signs.

The outliers in the fastest speed classes in Fig. 5 reveal extreme departures between the modeled and observed wind speeds. At a location in West Texas with measured wind speeds reaching 30 m s\(^{-1}\) at 40 m, the WIND Toolkit, ERA5, and MERRA-2 underestimate the observed wind speeds above 20 m s\(^{-1}\) by \(-20.7\) m s\(^{-1}\), \(-19.5\) m s\(^{-1}\), and \(-18.5\) m s\(^{-1}\), respectively. The positive bias outliers at speeds 15 m s\(^{-1}\) or greater, i.e., cases where the models overestimate faster observed wind speeds, are associated with coastal and mountainous locations.
### 3.2 Energy Production Validation

Wind speed models are the essential foundations for wind energy production estimation, and identifying uncertainties and trends in the former provides a similar starting point for evaluating the accuracy and representativeness of the latter. With the baseline wind speed error metrics established, the validation continues with an examination into the performance of three tools that utilize wind resource models to provide energy production estimates for small wind turbines, namely SAM, Wind Report, and MyWindTurbine.com. The annual energy production estimates (conveyed via capacity factors) are produced using the default wind resource data included with each tool and are net estimates that incorporate the default loss assumptions unique to each tool (Table 3). The default wind resource data for SAM is the WIND Toolkit, which was evaluated in Sect. 3.1. Wind Report employs wind resource data from 3Tier with a similar spatial resolution to SAM. MyWindTurbine.com utilizes wind information from the Global Wind Atlas 1.0, which has a similar spatial resolution to MERRA-2.

The differences between the simulated and observed capacity factors across 55 turbines are displayed in Fig. 6a. SAM, Wind Report, and MyWindTurbine.com all tend to overestimate the observed energy production, a divergence from the near zero average biases noted for the wind speed models, including the WIND Toolkit used by SAM. SAM and Wind Report perform similarly, with average capacity factor errors (simulated minus observed capacity factor) of +2.5 and +4.2 percentage points, respectively, and standard deviations of 6.0 and 7.1 percentage points, respectively. MyWindTurbine.com shows greater overprediction and more variability in the estimates with an average capacity factor error of +11.5 percentage points and a standard deviation of 8.8 percentage points. A one-sample t-test confirms that SAM is the best performing tool in terms of capacity factor error, with a 95% confidence interval of 0.8 – 4.1 percentage points. Wind Report has a 95% confidence interval of 2.2 – 6.1 percentage points and MyWindTurbine.com has a 95% confidence interval of 9.1 – 13.8 percentage points.

![Figure 6](https://doi.org/10.5194/wes-2021-111)

**Figure 6.** (a) Capacity factor error (simulated minus observed capacity factor) and (b) simulated annual average wind speed according to SAM, Wind Report, and MyWindTurbine.com across 55 small wind turbines. The median values are indicated with the red lines, the 25th and 75th percentiles form the blue boxed range, the minimum and maximum error metrics, excluding outliers, are in black, and outliers are indicated with red plus signs.
One cause for discrepancies in energy production estimates across the tools and relative to observations is the underlying wind resource information. SAM, Wind Report, and MyWindTurbine.com are each driven by wind resource datasets with different resolutions (Table 3) and physical assumptions. Fig. 6b shows the range of annual average wind speeds produced by each tool for each of the 55 turbines in the validation study. On average, MyWindTurbine.com produces faster wind speed estimates (5.7 m s\(^{-1}\)) with greater variability than SAM and Wind Report, which produce annual average wind speed estimates of 5.1 m s\(^{-1}\) and 5.2 m s\(^{-1}\), respectively. The maximum difference among the annual average wind speed estimates produced by the tools (0.6 m s\(^{-1}\)) is similar to the maximum difference in mean model wind speed bias (between the WIND Toolkit and ERA5) noted in Sect. 3.1 (0.7 m s\(^{-1}\)). The t- and Wilcoxon tests reveal significant differences in both simulated annual average wind speed and capacity factor error among the tools. The simulated wind speed is likely a contributor to the greater energy production overestimation using MyWindTurbine.com noted in Fig. 6a.

When exploring capacity factor error for the different small wind turbines, capacity factor error is found to become increasingly positive as the turbine rated capacity increases for SAM and Wind Report, as seen in Fig. 7a. No such trend is noted for MyWindTurbine.com. Similarly, Fig. 7b shows that the SAM and Wind Report capacity factor errors become increasingly positive as turbine hub height increases, again with no trend noted for MyWindTurbine.com.

The tools perform differently relative to each other in different regions of the United States (Fig. 7c). The greatest capacity factor errors produced by SAM are concentrated in the Northeast, with capacity factor errors exceeding +10 percentage points at four turbines in New York (one along the Lake Ontario coast, one along the Atlantic coast, and two in hilly terrain). Wind Report similarly overestimates observed energy production by more than +10 percentage points at a variety of turbines in the Northeast and significantly underestimates observed energy production (capacity factor error < -10 percentage points) at a coastal California turbine and a turbine located in a hilly area of Vermont. MyWindTurbine.com, noted for generating the greatest turbine energy production overestimates, performs more similarly to SAM and Wind Report in the Midwest and shows the greatest capacity factor error in the Northeast. SAM shows the least variability in performance error in the Southeast, while Wind Report and MyWindTurbine.com show the least variability in performance error in the Southern Plains.

The large capacity factor errors noted in areas of complex terrain and coastal interaction are consistent with the large model wind speed errors noted for these terrain types in Sect. 3.1. Given that high relative elevation locations and coastal environments tend to exhibit enhanced wind resource (NREL 2021b), making them favorable choices for small wind deployment, these results urge model and tool users to be especially cautious in these locations and to utilize the error metrics presented here to adjust energy production expectations.
Figure 7. Capacity factor error (simulated minus observed capacity factor) according to (a) turbine type, (b) hub height, and (c) region across 55 small wind turbines. The median error metrics are indicated with the red lines, the 25th and 75th percentiles form the blue boxed range, the minimum and maximum error metrics, excluding outliers, are in black, and outliers are indicated with red plus signs.

In addition to the challenge in energy production estimation in areas of complex terrain and/or coastal interaction, potential other sources of discrepancy in simulated energy production performance exist. Additional potential sources of discrepancy explored in the following sections include interannual variability in the wind resource (due to the wind datasets spanning different years), tool diversity in the handling of height adjustment between the model data and the desired hub height, and the representativeness of the different loss assumptions employed by each tool.
3.2.1 Impact of Interannual Wind Speed Variability on Energy Production Estimates

One of the model wind resource aspects that contributes to discrepancies in energy production estimates is interannual variability. Simple tools build annual average wind resource datasets based on individual years of wind data, averaged multi-year wind data, or a typical meteorological year, the last of which aims to represent a range of weather phenomena while maintaining an annual average similar to a longer-term average. Since the wind resource at a given location varies from year-to-year, the representativeness of the wind data employed by a tool will similarly vary from year-to-year. Interannual variability is found to significantly contribute to the uncertainty in tool-based energy production estimates, as explored in Fig. 8. For the 55 small wind turbines, SAM is run using each of the seven years of available WIND Toolkit data (2007-2013), of which 2013 is the default selection within the tool. At each site, we calculate the difference between the maximum and minimum capacity factor achieved in the ensemble of the seven runs. Fig. 8 shows that interannual variability in the wind resource is responsible for up to 6.5 percentage points of difference in simulated capacity factors, with an average of 3 percentage points. The observational discussion in Sect. 2 provides important context for the large impact interannual wind speed variability has on discrepancies in energy production estimates. The annual average wind speed observations in Fig. 1a range from 2 m s\(^{-1}\) to 9 m s\(^{-1}\), which aligns with the steepest portions of the small wind turbine power curves in Fig. 2c. This information, combined with the observed interannual wind speed differences up to 3 m s\(^{-1}\) reported in Sect. 2.1, provides a clear picture of how sensitive small wind turbines are to variability in the wind resource.

3.2.2 Impact of Vertical Interpolation on Energy Production Estimates

A further aspect of the wind resource that contributes to discrepancies in energy production estimates is the vertical interpolation technique employed in tool calculations. Two of the tools considered in this study, SAM and Wind Report, employ the power law (Eq. 1) to adjust wind resource data to a user-defined hub height. The shear exponent \(\alpha\) (Eq. 2) expresses the shape of the vertical wind speed profile and is used to interpolate or extrapolate wind speed output from one or more vertical levels to another. Observationally, the shear exponent varies diurnally, seasonally, geographically, and according to
atmospheric stability. However, simple energy production estimation tools typically employ a single value to characterize the vertical wind speed profile and adjust wind speeds to a desired hub height. This practice can lead to mischaracterizations of the actual wind resource at a site of interest, warranting exploration into the degree of impact vertical interpolation has on energy production estimation.

For energy production simulations incorporating wind speed data at a single height, SAM employs a default shear exponent of 0.14, reflecting the commonly-used 1/7 law, which is an empirically-estimated shear exponent that assumes smooth terrain and neutral atmospheric conditions. Others in the wind energy community, including members involved in resource assessment and wind turbine design, have migrated to using a larger shear exponent of 0.2 (Storm and Basu, 2010), which is close to the default value of 0.18 employed by Wind Report. For energy production simulations incorporating wind speed data at heights surrounding the user-defined hub height, SAM employs linear interpolation to vertically adjust wind speed data from the surrounding model heights to the height of interest.

The impact of interpolation techniques on the resultant energy production estimates produced by SAM is found to be minimal, as presented in Fig.9. For each of the 50 small wind turbines that require model wind speed adjustment to hub height, SAM is run (1) using the power law in conjunction with the nearest neighbor WIND Toolkit height and a shear exponent of 0.14, (2) using the power law in conjunction with the nearest neighbor WIND Toolkit height and a shear exponent of 0.18, (3) using the dynamic power law of Eq. (1) with the two surrounding WIND Toolkit heights, and (4) using linear interpolation of the two surrounding WIND Toolkit heights. As in the interannual variability study, at each site we calculate the difference between the maximum and minimum capacity factor produced by the four approaches. Fig. 9 shows that for the majority of the small wind turbines considered in this study, choice of vertical interpolation technique is responsible for less than 1 percentage point. The maximum difference in capacity factor according to vertical interpolation technique is 3.7 percentage points, with an average of 1.4 percentage points.

Figure 9. Maximum minus minimum SAM simulated capacity factor based on wind resource data adjusted via four vertical interpolation techniques across 50 small wind turbines. Five small wind turbines are redacted from the analysis since their hub heights directly align with a WIND Toolkit output height, thus eliminating the need for vertical interpolation.
3.2.3 Turbine Availability

A subset of the 55 turbines include information on the amount of time each spent in the following states: (1) running, (2) waiting for wind, (3) stopped/fault, and (4) missing, the last of which is estimated by comparing the number of actual versus expected annual reports each turbine produces. Fig. 10 displays the annual average percentages of each operational state that nine turbines experience. The turbines are diverse in geography and age, with representation in each major geographic region in the continental U.S. and observations spanning one to ten years.

While the states of running and waiting for wind are related to the available wind resource, the remaining states of stopped/fault and missing can provide observational comparisons for the loss assumptions employed by the energy production estimation tools. The amount of time the turbines are in a stopped/fault ranges from 0% to 6% and the amount of missing data ranges from 0% to 13%. The amount of time missing or spent in a stopped/fault state combined ranges from 0% to 19%, encompassing all of the default loss assumption percentages from the tools, namely SAM with 18% loss, Wind Report with 10% loss, and MyWindTurbine.com with 7% loss. In other words, the loss assumptions employed by the tools are representative of actual small wind turbine losses. Across the turbines, the average amount of time missing or spent in a stopped/fault state is 9%, a percentage closest to the loss assumption employed by Wind Report.

Figure 10. Annual frequency of time that nine turbines are in states of running, waiting for wind, stopped/fault, or are missing data.
4 Conclusions

An initial investigation of wind speed accuracy from three commonly used models or reanalysis products (WIND Toolkit, ERA5, and MERRA-2) at small wind turbine heights (10 m – 50 m) yielded average biases within ±0.5 m s⁻¹ and average MAEs less than 2 m s⁻¹. However, a small wind adopter located in an area of complex terrain (hills, mountains, or coastal environments) should anticipate wind speed bias magnitudes and MAEs up to 5 m s⁻¹. In agreement with trends noted by Gruber at al. (2019) and Duplyakin et al. (2021), most model wind speed error metrics tend to be consistent regardless of horizontal interpolation technique for each of the three models assessed. The results also show that the WIND Toolkit, ERA5, and MERRA-2 overestimate observed wind speeds slower than 5 m s⁻¹, a range that encompasses most turbine cut-in wind speed ranges, which can lead to energy production overestimates. Conversely, the three models tend to underestimate larger observed wind speeds, which can impact energy production estimates by underpredicting the amount of time spent at peak power and by underestimating the amount of turbine cut-out events.

Using actual turbine production data, three user-friendly energy production estimation tools (SAM, Wind Report, and MyWindTurbine.com) were shown to overpredict actual turbine performance. Using the default settings, SAM and Wind Report overestimate observed turbine production within 5 percentage points, while MyWindTurbine.com overestimates observed turbine production by 11.5 percentage points. The underlying wind speed data utilized by MyWindTurbine.com, which has a spatial resolution similar to MERRA-2, was on average 0.5 m s⁻¹ faster than the wind speed data utilized by SAM and Wind Report, accounting for some of the discrepancy in energy production estimates among the models. SAM employs the WIND Toolkit for wind speed data and Wind Report uses wind speed information at a similar spatial resolution to the WIND Toolkit. Similar to the simulated wind speed estimates from WIND Toolkit, ERA5, and MERRA-2, the energy production estimation tools exhibited challenges in complex terrain, overestimating or underestimating the observed turbine production by more than 10 percentage points in some hilly and coastal regions. The default loss assumptions within SAM, Wind Report, and MyWindTurbine.com (18%, 10%, and 7%, respectively) fell within the observed combined stopped/fault and missing losses reported by actual turbines, which ranged from 0% to 19% with an average of 9%, indicating realistic loss representation across the tools, despite their diverse percentages.

Choice of wind speed reference year(s) yielded significant influence on turbine production estimates (3 percentage points on average, with a maximum of 6.5 percentage points). Contrastingly, choice of vertical interpolation technique for wind speed adjustment yielded minimal influence on turbine production estimates (1.4 percentage points on average, with a maximum of 3.7 percentage points), consistent with the findings of Olauson (2018) and Duplyakin et al. (2021).

Continuing advances in wind speed models, such as the recent updates to the WIND Toolkit (Pronk et al., 2021) and the Global Wind Atlas (2021), the models employed by SAM and MyWindTurbine.com, respectively, are critical to reducing uncertainty in wind resource estimates and are anticipated to similarly reduce uncertainty in energy production estimates when they are incorporated into simulation tools. Reduced uncertainty can improve customer confidence in the ability of small wind turbines to generate energy and thus increase financing opportunities for small wind projects, ensuring that small wind turbines
can continue to have a role in decarbonizing the U.S. economy and in addressing the challenges of energy accessibility, equity, and security endured by rural and underrepresented communities. In addition to setting expectations for current users, the results of this study provide baselines of comparison for future versions of wind speed models, reanalyses, and energy production simulation tools.

**Code and Data Availability**

Much of the wind speed measurement data that supports this study is openly available. Sodar-based wind speed observations from the first Wind Forecast Improvement Project are available at https://a2e.energy.gov/projects/wfip1. The near surface wind speed measurements from the National Centers for Environmental Information are available at https://www.ncei.noaa.gov/access/search/data-search/global-hourly. Coastal wind speed observations from the National Data Buoy Center are found at https://www.ndbc.noaa.gov/. Meteorological tower data from Argonne National Laboratory are available at https://www.atmos.anl.gov/ANLMET/. Brookhaven National Laboratory meteorological data are provided at https://wx1.bnl.gov/. Meteorological tower data from NREL are found at https://www.nrel.gov/wind/nwtc/data.html.

Meteorological tower observations from Oak Ridge National Laboratory are available through the Lawrence Berkeley National Laboratory interface at https://ameriflux.lbl.gov/sites/. Observations from Savannah River National Laboratory are available via the B2SHARE Tall Tower Dataset at https://b2share.eudat.eu/records/159158152f4d4be79559e2f3f6b1a410. Wind speed data from the Bonneville Power Administration network of meteorological towers is available at https://transmission.bpa.gov/Business/Operations/Wind/MetData/default.aspx. Wind resource data from the University of Massachusetts can be found at https://www.umass.edu/windenergy/resourcedata. Meteorological tower data from Pacific Northwest National Laboratory are in the process of being uploaded to https://a2e.energy.gov/ and for the present are available upon request from the lead author. The remaining wind speed observational collections are proprietary and were used under license for this study and therefore are not publicly available.

The turbine production data are available for collaboration opportunities upon a case-by-case basis. If interested, please contact the lead author.

Scripts for data quality control, statistical analysis, and plotting are available from the lead author upon request.
Author Contributions

LS wrote the manuscript and led the analysis with significant contributions from CP. CP was also instrumental in the acquisition of wind speed observations. AO conceptualized the project, was instrumental in the acquisition of turbine performance data, and provided feedback on the methodology and draft. LB and HT conceptualized the project and provided feedback on the methodology and draft. RR provided guidance on the methodology and feedback on the draft. SZ, DD, and JF provided guidance on the methodology.

Competing Interests

The authors declare that they have no conflicts of interest.
