**Abstract.** Atmospheric stability has a significant effect on wind shear and turbulence intensity, and these variables, in turn, have a direct impact on wind power production and loads on wind turbines. It is therefore important to know how to characterize atmospheric stability in order to make better energy yield estimation in a wind farm.

Based on research grade meteorological mast at Alaiz (CENER's Test Site in Navarre, Spain) named MP5, this work compares and evaluates different instrument set-ups and methodologies for stability characterization, namely: the Obukhov parameter  $\zeta = z/L$ , which can be measured locally with the use of a sonic anemometer, and the bulk Richardson number have been studied based on two temperature and one wind speed measurements. The methods are examined considering their theoretical background, implementation complexity, instrumentation requirements, and practical use in connection with wind energy applications. The sonic method provides a more precise local measurement of stability while the bulk Richardson is a simpler, robust and cost-effective technique to implement in wind assessment campaigns. Using the sonic method as a benchmark, it is shown that to obtain reliable bulk Richardson measurements in onshore sites it is necessary install one of the temperature sensors close to the ground where the temperature gradient is stronger.

Bulk Richardson number, which is based on one height wind speed measurement and two temperature measurements, is sometimes calculated using values from any two temperature levels without taking into account that one of the measurements would be representative of surface conditions. With the data available in MP5, it will be shown how this approximation is not correct to obtain an adequate stability characterization.

General comments, English

## 1. Introduction

The vertical wind profile and the turbulence intensity in the atmospheric boundary layer (ABL) are two of the main physics aspects driving wind energy production and turbine loads, the features that most affect the wind energy generation. The vertical wind profile is especially important since rotors are getting bigger and hub heights are getting higher making it invaluable to know the wind speed at hub height. The vertical wind profile shape and turbulence intensity can directly influence wind turbine production but also wind turbine loads, affecting the wind turbines lifetime. The wind profile because given the growing hub heights and rotor sizes of the modern wind turbines it affects the wind turbine production and loads; and the turbulence intensity because it induces loads that the wind turbine will support over its design lifetime. Despite the fact that the IEC standard (IEC61400-1 (ED4) 2019, 2019) specifies a power law vertical model independent of atmospheric stability to perform load calculations, the dependence of this and, in turn, the turbulence intensity with atmospheric stability is widely demonstrated (Emeis, 2013; Lange et al., 2004b; Peña and Hahmann, 2012). In addition several studies have demonstrated the impact of atmospheric stability on wind resource assessment (Lange et al., 2004a), wind turbine power curves and Annual Energy Production (AEP) calculations (Martin et al., 2016; Schmidt et al., 2016); wind turbine loads (Kelly et al., 2014; Sathe et al., 2013) and wind turbine wakes (Abkar and Porté-Agel, 2015; Hansen et al., 2010; Macheaux et al., 2016). This is why the wind industry is developing models and methods to include the effect of atmospheric stability in the layout design and energy yield assessment. These methodologies and models require the characterization of the probability distribution of atmospheric stability at each site. Therefore different methods and parameters are used to describe atmospheric stability without an industry-wide convention about which one is the most appropriate.

**Comentario [ECN4]:** Answer RC2  
Technical corrections.

According to Monin and Obukhov similarity theory (MOST) (Foken, 2006; Monin and Obukhov, 1954) stability can be estimated in terms of inverse of Obukhov length that can be calculated with vertical fluxes of heat and momentum obtained with the eddy covariance method. To obtain the necessary high-frequency measurements of

49 wind speed vector components and temperature, sonic anemometers are used, which is why this calculation method  
50 is called "sonic method".

51 Another measure for stability is the Richardson number that as Bardal (Bardal et al., 2018) explains according to  
52 Stull book (Stull, 1989) has several formulations: the flux Richardson number, gradient Richardson number and  
53 bulk Richardson number. The latter is based on one height wind speed measurement and two temperature  
54 measurements, one from the air at one height and the other from the ground or water surface.

55 In the wind energy context some studies have been done about how to measure the stability and their influence in  
56 the turbulence intensity and vertical wind profile. However, most of these studies have been carried out in offshore  
57 sites (Peña and Hahmann, 2012; Sanz Rodrigo et al., 2015; Sathe et al., 2011) finding relationships (Grachev and  
58 Fairall, 1997) between the Obukhov length and the Richardson bulk number that, facilitate the characterization of  
59 stability without the need of sonic anemometer. This is convenient, because although the sonic anemometer has  
60 many advantages (Cuerva et al., 2006), This is convenient to avoid the they added complexity, in terms of use and  
61 data management, and cost, ten times higher than cup anemometers, of these instruments into the long-term site  
62 assessment campaigns.

Comentario [ECN5]: Answer RC2  
specific comments.

63 For onshore sites there are few studies that analyse how to characterize atmospheric stability and those that exist  
64 are on simple topography in coastal areas (Bardal et al., 2018).

65 Although the behaviour of wind flow over complex terrain is widely studied, as Finnigan summarizes in  
66 (Finnigan et al., 2020) and there are recent publications about the influence of atmospheric stability in wind farms  
67 located in complex terrain (Han et al., 2018; Radünz et al., 2020, 2021); there are no references that analyse in detail  
68 how to characterize atmospheric stability according to different instrumentation requirements.

69 Measuring atmospheric stability in complex terrain has some challenges (compared to flat terrain), one of them  
70 is the fact that the MOST is developed for horizontally homogeneous and flat terrain and in complex terrain vertical  
71 wind speed can be due to stability or sloping terrain, therefore, vertical fluxes will be "contaminated" by terrain  
72 effects. This can be mitigated by using good measurement practices (data quality, coordinate systems and post  
73 processing options) (Stiperski and Rotach, 2015).

74 This study presents atmospheric stability characterization from one mountainous site obtained using two  
75 methods: sonic method and the Richardson bulk number. Measurements of different heights have been used to see  
76 the influence of this parameter on the results

77 The place used in this study meets the characteristics of a typical complex terrain site for wind energy  
78 deployment. The 118 m high MP5 reference meteorological mast, as is explained in other articles by Sanz (Sanz  
79 Rodrigo et al., 2013) and Santos (Santos et al., 2020), is equipped with wind (cup and 3D sonic anemometer) and  
80 temperature measurements distributed along six vertical levels: 2, 40, 80, 90, 100 and 118 m above the ground level  
81 (a.g.l), enabling the comparison between Richardson bulk number and the sonic method to evaluate atmospheric  
82 stability.

83 Special focus is given to explaining the post-processing methodologies to derive stability from raw data  
84 considering fast-response sonic anemometer in a complex terrain.

## 85 2. Atmospheric stability definitions

### 86 2.1 The Obukhov length

87 Monin and Obukhov (M-O) (Monin and Obukhov, 1954) introduced the Obukhov length  $L$  to characterize  
88 atmospheric stability, which is proportional to the height above the surface at which the production of turbulent  
89 energy from buoyancy dominates over mechanical shear production of turbulence (Stull, 1989), and it is defined as:

$$L = -\frac{u_*^3}{\kappa \frac{g}{\Theta_0} w' \theta'} \quad (1)$$

Comentario [ECN6]: Answer RC2  
Technical corrections

90 Where  $g=9.81 \text{ ms}^{-2}$  is the acceleration due gravity,  $\kappa = 0.41$  is the von Karman constant,  $u_*$  is the friction  
91 velocity,  $\Theta_0$  is the surface potential temperature and  $w' \theta'$  is the heat flux. The dimensionless height  $\zeta = z/L$  is used  
92 as stability parameter, where  $\zeta < 0$  indicates unstable,  $\zeta > 0$  stable and  $\zeta = 0$  neutral conditions.

Comentario [ECN7]: Answer RC2  
Technical corrections.

Comentario [ECN8]: Answer RC2  
Technical corrections.

93 Table 1 shows the Sorbjan & Grachev (Sorbjan and Grachev, 2010) stability classification proposing, they  
94 identify four regimes in the stable conditions boundary layer. This classification is also followed by Sanz (Sanz

Rodrigo et al., 2015) assuming a symmetric classification in the unstable range. Sanz Rodrigo *et al.* shift the "extremely unstable and stable" regime limit to  $|\zeta| = 1$  in order to avoid contamination of the large scatter found in the high ends of the scale to the "very unstable and stable" class. An additional limit is added at  $|\zeta|=0.2$  to give higher resolution in the most frequent stability range. For consistency, we shall adopt the same classification used in (Sanz Rodrigo et al., 2015) to facilitate the comparison with offshore conditions.

**Comentario [ECN9]:** Answer RC2  
General comments, English

**Comentario [ECN10]:** Answer RC2

**Comentario [ECN11]:** Answer RC2  
Technical corrections.

**Table 1** Classification of atmospheric stability adapted from (symmetric for the unstable range) (Sorbjan and Grachev, 2010).

Stability Class	Stability parameter $\zeta = z/L$
<u>extremely unstable (xu)</u>	$\zeta < -1$
<u>very unstable (vu)</u>	$-1 < \zeta < -0.6$
<u>unstable (u)</u>	$-0.6 < \zeta < -0.2$
<u>weakly unstable (wu)</u>	$-0.2 < \zeta < -0.02$
near-neutral (n)	$0 < \zeta < 0.02$
weakly stable (ws)	$0.02 < \zeta < 0.2$
stable (s)	$0.2 < \zeta < 0.6$
very stable (vs)	$0.6 < \zeta < 1$
extremely stable (xs)	$\zeta > 1$

**Comentario [ECN12]:** Answer RC1  
corrections.

**Comentario [ECN13]:** Answer RC2  
Specific comments

Using sonic anemometers and eddy covariance technique, the Obukhov length can be obtained. In this way, stability is evaluated locally based on turbulent fluxes averaged over periods from minutes to one hour to integrate the kinetic energy in the microscale turbulence range.

Sonic anemometer can be used in complex terrain to derive the local Obukhov length. Following the planar fit method of Wilezak et al. (Wilezak et al., 2001), momentum fluxes should be calculated in the mean streamline plane and heat fluxes in the true vertical coordinate system. If the streamline plane can be known a priori, from a wind direction sector with uniform slope, the planar fit method can be used to infer the mounting tilt angle and correct for it to reduce the uncertainty on the vertical fluxes.

## 2.2 Bulk Richardson number

The bulk Richardson number  $Ri_b$  is a form of the Richardson number that is widely used for characterizing stability for its simplicity, defined in terms of a (potential) potential temperature difference and a single velocity level:

$$Ri_b = -\frac{gz\Delta\theta}{\theta_0\overline{U^2}} \quad (2)$$

**Comentario [ECN14]:** Answer RC2  
Technical corrections.

Where, as proposed Sanz et al. in (Sanz Rodrigo et al., 2015), the height  $z$  is taken here as the mean height between the two levels of temperature and  $\Delta\theta$  is derived from the water-air or surface-air temperature difference.

As Bardal et al. propose in (Bardal et al., 2018) propose the general empirical relations from Businger et al. (Businger et al., 1971) slightly modified by Dyer (Dyer, 1974) have been used to relate  $\zeta$  with the  $Ri_b$ :

$$\xi = \begin{cases} Ri_b, & Ri_b < 0 \\ \frac{Ri_b}{1-5Ri_b}, & 0 < Ri_b < 0.2 \end{cases} \quad (3)$$

**Comentario [ECN15]:** Answer RC2  
Technical corrections.

**Comentario [ECN16]:** Answer RC2  
Technical corrections.

Alternatively  $Ri_b$  can be used directly to do a stability classification. (Mohan, 1998) has proposed a seven classes of stability classification methodology (Table 2) which has been accepted by the scientific community as it was shown. Alternatively by  $Ri_b$  can be used directly to do a stability classification, according to Mohan (Mohan, 1998) which classification is used in literature (Ruisi and Bossanyi, 2019), based on seven classes of stability (Table 2).

**Table 2** Classification of atmospheric stability (Mohan, 1998).

Stability Class	Stability parameter $Ri_b$
Very unstable	$Ri_b < -0.023$
Unstable	$-0.023 \leq Ri_b < -0.011$
Weakly unstable	$-0.011 \leq Ri_b < -0.0036$
Neutral	$-0.0036 \leq Ri_b < 0.0072$

**Comentario [ECN18]:** Answer RC1  
corrections.

Weakly stable	$0.0072 \leq Rib < 0.042$
Stable	$0.042 \leq Rib < 0.084$
Very stable	$Rib \geq 0.084$

128 **3. The Alaiz site**

129 The MP5 mast is located (42°41.7' N, 1°33.5' W) at the top of Alaiz mountain in the region of Navarre (Spain),  
 130 around 15 km SSE from Pamplona in the CENER's experimental wind farm. The prevailing wind directions are  
 131 from the North and from the South. To the North there is a large valley at around 700 m lower altitude. To the  
 132 South, complex terrain is found with the presence of some wind farms; the closest one situated 2 km behind the row  
 133 of six wind turbine stands of the test site (see Fig. 1). [As it is explained by](#) (Sanz Rodrigo et al., 2013) [the wakes](#)  
 134 [from this wind farm can be considered well mixed with the boundary layer flow in most conditions so additional](#)  
 135 [turbulence it is not expected in MP5 due wakes from neighbour wind farms.](#)

**Comentario [ECN19]:** Answer RC2  
 Specific comments

136 Besides MP5 meteorological mast there are four other reference met masts (MP0, MP1, MP3 and MP6), all of them  
 137 118 m tall.

138 The test site started operating in 2009 with the site calibration procedures. The first wind turbines were installed  
 139 in the summer of 2011. The standard configuration of each mast is designed for multi-megawatt wind turbine testing  
 140 and includes sonic and cup anemometer, wind vanes and temperature/humidity measurements. Replicated cup  
 141 anemometers are situated 2 m below the reference ones.

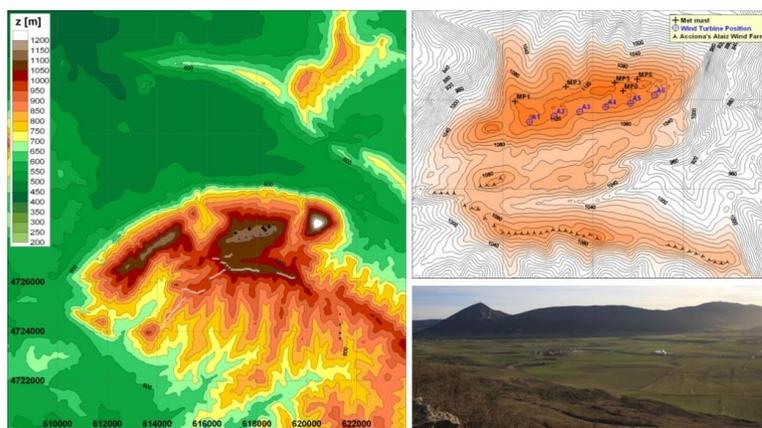

142 The mast MP5 is 118 m high lattice permanent mast with nine measurement levels with booms oriented to the  
 143 West (263°) and the East (83°). Wind speed and wind direction are measured at five levels (118, 102, 90, 78 and 40  
 144 m) with cups anemometer (oriented to the West) and wind vanes (oriented to the East); while sonic anemometer are  
 145 installed at 115.5, 75.5 and 39.5 m (oriented to the West). Temperature and relative humidity are measured at five  
 146 levels (113, 97, 81, 38 and 2 m) and pressure at 2 m high.

147 The instrumental set-up is compliant with IEC 61400-12-1(IEC61400-12-1 (ED1) 2005-12, 2005) with  
 148 MEASNET cup anemometer calibration (Measnet, 2009) and with ENAC accreditation according to UNE-EN  
 149 ISO/IEC 17025.

150 The data acquisition system consist in a real-time controller CompactRIO from National Instruments with 128  
 151 MB DRAM and 2 GB storage embedded in a chassis in connection with 8 modules of digital and analogical data  
 152 acquisition. All connected to an Ethernet network.

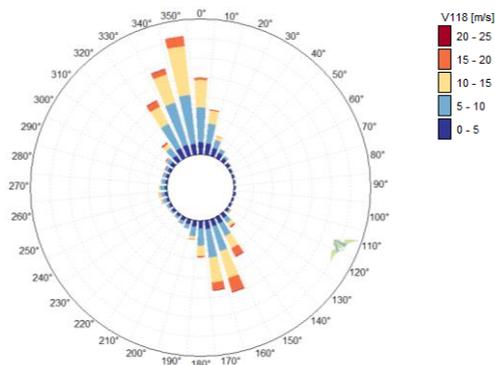

153 The rate sample is 5 Hz for cup anemometer (Vector A100LK) and 20 Hz for sonic anemometer (METEK USA-  
 154 1), wind vanes (Thies Compact), pressure (Vaisala PTB100A), and humidity temperature sensor (Ammonit P6312).

155 Figure 2 shows the wind rose at the MP5 site, from the period between July 2014 to June 2015. It presents a  
 156 bidirectional wind climate, with prevailing winds from the north-northwest sector (330–360, 32% of total) and the  
 157 south southeast sector (150–180, 28% of total).

158 **Figure 1** Alaiz elevation map, close-up of the test site and view from the upstream ridge to the North.

158  
 159  
 160

161 **Figure 2** Wind rose of 10 min wind speeds observed by MP5 at 118m for the reference period (July 2014–June 2015).

162 **4. Methodology**

163 In the present work, a one year period (1st July 2014 to 30th June 2015) is analyzed. [Measurements–Flux](#)  
 164 [measurements](#) from the sonic anemometer at 115.5, 75.5 and 39.5 m are used to calculate de Obukhov length  $L$ ,  
 165 while conventional sensors (wind direction, relative humidity, air pressure and temperature) are used to estimate the  
 166 bulk Richardson number.

**Comentario [ECN20]:** Answer RC2  
 Technical corrections.

167 **4.1 Data quality control**

168 Before calculating stability parameter all data are checked for data quality.

169 Data from conventional sensors (wind direction, relative humidity, air pressure and temperature) have been  
 170 processed following Brower (Brower, 2012). It consists on checking the completeness of the collected data and  
 171 applying several test (range, relational and trend). After filtering for quality-control purposes, the conventional  
 172 sensors provide horizontal wind speeds, directions, relative humidity, pressures and temperatures availabilities  
 173 greater than 85% at all levels during the evaluation period.

174 For sonic anemometer there are a lot of procedures (Aubinet et al., 2012) and test criteria for quality control of  
 175 turbulent time series and studies about the impact in the results of this procedures (Stiperski and Rotach, 2015).

176 High-frequency raw data often contain impulse noise, that is, spikes, dropouts, constant values, and noise. Spikes  
 177 in raw data can be caused by instrumental problems, such as imprecise adjustment of the transducers of ultrasonic  
 178 anemometer, insufficient electric power supply, and electronic noise, as well as by water contamination of the  
 179 transducers, bird droppings, cobwebs, etc., or rain drops and snowflakes in the path of the sonic anemometer.

180 Several spikes in wind speed have been detected in the raw sonic anemometer data. Therefore, a de-spiking filter  
 181 is applied based on the change in wind speed from each data point to the next and taking into account the physical  
 182 limits according to sensor specifications. Data points are removed if they are preceded and followed by changes  
 183 exceeding the lowest 99% of all changes. After filtering the spikes, the sonic anemometer provide wind speed and  
 184 temperature availabilities greater than 80% in the three sonic anemometer.

185 **4.2 Eddy Covariance method**

186 The operating principles of sonic anemometer are described by different authors (Aubinet et al., 2012; Cuerva et al.,  
 187 2003; Kaimal and Businger, 1963; Kaimal and Finnigan, 1994; Schotanus et al., 1983). The sonic anemometer  
 188 output provides three wind components in an orthogonal axis system and sonic temperature. The relation between  
 189 sonic temperature and absolute real temperature is given by [Kaimal & Gaynor](#) (Kaimal and Gaynor, 1991).

190 High frequency data from sonic anemometer have been processing to obtain 10 minutes databases that include  
 191 turbulent fluxes of energy, mass, and momentum with the eddy covariance technique (Aubinet et al., 2012)(Burba,  
 192 2013; Burba and Anderson, 2010; Geissbühler et al., 2000).

193 The main requirements for instruments and data acquisition systems used for eddy covariance data are their  
 194 response time to solve fluctuations up to 10 Hz. This means that the sampling frequency has to be high enough to

195 cover the full range of frequencies carrying the turbulent flux, leading usually to a sampling rate of 10–20 Hz. In the  
 196 test case in this report 20 Hz is the sample rate for the sonic anemometer.

197 The transformation of high-frequency signals into means, variances, and covariances requires different steps  
 198 (Aubinet et al., 2012; Stiperski and Rotach, 2015), in this study the next steps ~~has~~ have been proposed:

**Comentario [ECN21]:** Answer RC2  
 Technical corrections.

- 199 1. Quality Control of raw data, explained in point 4.1.2
- 200 2. Coordinate Rotation, transformation of coordinate systems, from the original axes based on the anemometer  
 201 output to the streamline terrain-following system, based on the Planar Fit Method (PFT) (Richiandone et al.,  
 202 2008; Wilczak et al., 2001). Momentum fluxes and heat fluxes have been calculated with respect to the  
 203 streamline terrain-following coordinate system. Figure 3 shows the steps to rotate the axes from mounting  
 204 coordinates to streamline coordinates.

**Comentario [ECN22]:** Answer RC2  
 Specific comments

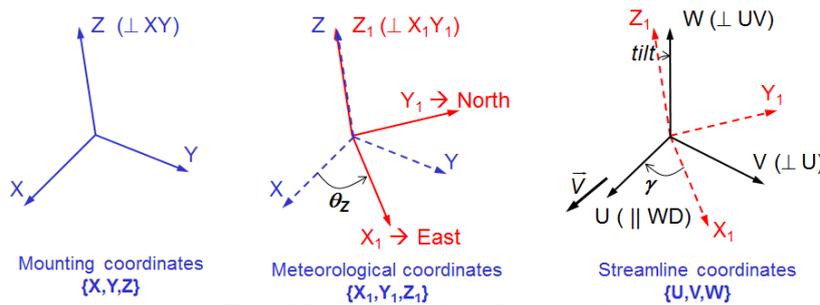

Figure 3 Schematic description for the rotation process.

- 205
- 206 3. Variance and Covariance Computation, apply eddy covariance technique for calculation of vertical turbulent  
 207 fluxes (heat and momentum). It corresponds to the calculation of the covariance of the fluctuations of the vertical  
 208 velocity with the quantity  $\Phi$  (temperature for heat, velocity components for momentum).

$$F_{\phi} = \overline{w'\phi'} = \overline{w\phi} - \overline{w}\overline{\phi} = \frac{1}{N-1} \left[ \sum w'\phi' - \frac{1}{N} (\sum w') (\sum \phi') \right] \quad (4)$$

209 N denotes the number of samples considered for the short averaging period T over which the flux is  
 210 calculated (from 5 to 60 minutes). N has to be long enough to ensure statistical convergence and short enough to  
 211 assume stationarity (in complex terrain difficult to fulfil both criteria). In this work a 10 minutes averaging period  
 212 has been selected.  
 213

214 In the MP5's sonic anemometer, at 115.5, 75.5 and 39.5 m height, moreover the temperatures, the variables  
 215 recorded are: the module of wind speed vector, the direction and vertical component (z). These values are projected  
 216 to meteorological coordinates to obtain the three components of wind speed vector (x, y, z) after being filtered the  
 217 transformation of high-frequency signals into means, variances, and covariances has been done.

218 The 10 minutes values of wind speed from sonic anemometer after applying steps 1 to 3 are checked and some  
 219 non-valid data are detected. As in conventional sensors these invalid data are due to icing effects so they are filtered.

#### 220 4.4 Stability assessment

221 MP5's sonic anemometer allowing allow evaluating stability based on the local Obukhov length at different heights.  
 222 This will be the benchmark method since it is directly obtained from the measurements without introducing any  
 223 assumptions or empirical relationships. The bulk Richardson number is evaluated as an alternative methodology  
 224 since it follows easier instrumentation set-up and post-processing, and for offshore places has presented good results  
 225 (Sanz Rodrigo, 2011; Sanz Rodrigo et al., 2015).

**Comentario [ECN23]:** Answer RC2  
 Technical corrections.

##### 226 4.4.1 Sonic method

227 To obtain the stability parameter  $\zeta = z/L$ , as it was explained before, sonic anemometer measurements are rotated to  
 228 the mean streamline coordinate system using the planar fit method to guarantee that the mean streamline plane will  
 229 be parallel to the terrain surface. After this, variances and covariances of detrended velocity and sonic temperature  
 230 perturbations are computed using the eddy covariance technique over high frequency timescale. Then, turbulent  
 231 fluxes are obtained by averaging the covariances over a period of 10 minutes.

232 In complex terrain, the hypothesis of a homogeneously horizontal surface layer is not fulfilled so the applicability of  
233 Monin and Obukhov similarity theory (MOST) to complex terrain conditions is not obvious. This signify that for the  
234 complex sites as Alaiz the theory is not completely valid because the topography creates local variations of wind  
235 flow near the ground (Kaimal and Finnigan, 1994).

#### 236 4.4.2 Bulk Richardson number

237 As it was explained before, sonic anemometry is not routinely used in wind energy, and bulk Richardson number  $Ri_b$   
238 is an alternative way to estimate atmospheric stability based on a temperature difference and a single velocity level  
239 (Eq. (2)).

240 In  $Ri_b$  number equation, potential temperature  $\theta$ , is the temperature of an air parcel with absolute temperature  $T$   
241 and pressure  $p$  would have if brought adiabatically to the pressure at the 1000 mb level. To first order it can be  
242 calculated as:

$$\theta = T + \left(\frac{g}{C_p}\right) \Delta z \quad (5)$$

243 Where  $g$  is the acceleration due gravity,  $C_p=1000 \text{ Jkg}^{-1}\text{K}^{-1}$  is the specific heat capacity of the air at constant  
244 pressure, and  $\Delta z$  is the height difference from the 1000 mb level.

245 With Eq. (3) the obtained  $Ri_b$  will be used to estimates the stability parameter  $\zeta = z/L$ . As Bardal *et al.* (Bardal  
246 *et al.*, 2018) explain, these formulations are only valid for values lower than 0.2, but to make a classification  
247 according to atmospheric stability they are considered adequate.

### 248 5. Results and discussion

249 The study is divided into two parts: statistics of atmospheric stability with both methods (the Obukhov length and  
250 Richardson Bulk); and comparison between both methods.

#### 251 5.1 Sonic method

252 Atmospheric boundary layer (ABL) models used in wind farm design tools are typically based on Monin-Obukhov  
253 theory. In stable conditions this surface-layer theory is extended to the entire ABL by assuming local scaling of  
254 turbulence characteristics through the stability parameter  $\zeta = z/L$ . This similarity theory would produce self-similar  
255 profiles of dimensionless quantities regardless of the height above ground level.

256 In the study case, as it was explained before, from the high-frequency (20 Hz) data recorded in the three  
257 available sonic anemometers in MP5 mast, the values of the Obukhov length ( $L$ ) over a period of 10 minutes have  
258 been obtained, and taking into account the heights at which they are installed, the parameter  $\zeta = z/L$ .

259 In Fig. 4 the stability parameter  $\zeta = z/L$  frequency distribution at the three sonic heights is depicted, resulting in  
260 showing a good agreement among them with a reduction of the percentage of conditions near neutral stability as the  
261 measurement height increases.

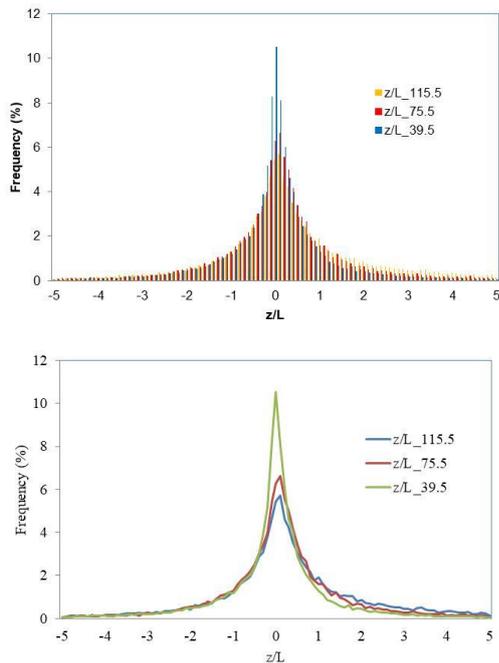

Figure 4 Probability distribution of  $z/L$  at all the sonic heights. Only concurrent time steps between July 2014 and June 2015 are included.

Figure 5 shows the distribution of atmospheric stability against wind speed at the MP5 measurements heights, the 9 stability classes propose in Table 1 are reduced to five combining: weakly unstable and stable classes with unstable and stable classes; and very unstable and stable with extremely unstable and stable. Table 3 shows the classification used. For the three heights, the stable situations are slightly higher than the unstable ones and there is an increase of neutral and stable conditions with increasing wind speeds, this is in accordance with the general knowledge that for strong wind speeds the atmosphere becomes neutrally stratified.

Table 3 According to Table 1 a reduced five stability classes.

Stability Class	Stability parameter $\zeta = z/L$
very unstable (vu)	$-\zeta < -0.6$
unstable (wu)	$-0.6 < \zeta < -0.02$
neutral (n)	$-0.02 < \zeta < 0.02$
stable (ws)	$0.02 < \zeta < 0.6$
very stable (vs)	$0.6 < \zeta$

As mentioned before, it is observed a significant dependence of stability distributions with height. At higher levels, the stability distributions are broader and there are more frequent cases with very large and extreme stability. This dependency of the stability distribution with height is because  $z$  is part of the definition of the stability parameter; and closer to the ground there are more "neutral" conditions because  $z/L$  tends to zero.

The variation of atmospheric stability with wind direction is showed in Fig. 8. Stable situations dominate in most of the directions except for the northwest direction (330°-350°) that is one of the predominant in Alaiz. [As can be seen in Fig. 1, the North face of Alaiz Mountain has a steep slope \(the Roughness Index \(RIX\) value in the north sector in MP5 position is 22.4%\) that empties into a large valley at around 700 m lower altitude. According to \(Stull, 1989\) this topography causes ascending hillside/valley winds that generate convective turbulence and therefore situations of instability that could explain some of the unstable conditions found in the 330°-350° direction sector.](#)

Following the stability classification defined in [Table 3 Table 4](#), Fig. 9 and Fig. 10 present the dependency of wind shear (calculated as the wind speed ratio between 118 and 40 m) and turbulence intensity (calculated as the ratio of the standard deviation to the mean wind speed at 118 m) with stability based on z/L parameter from the three sonic sensors installed for the NNW and SSE prevailing wind direction sectors.

308 For the three heights is observed that, as is explained by (Emeis, 2013), in unstable situations the ground surface is warmer than the air above so there is a positive heat flux that causes more turbulence. This results in a convective, well-mixed, surface layer with small vertical gradients. On the other hand, lower turbulence and high shear wind profiles are associated to stable situations where turbulence is reduced due to a negative vertical heat flux.

## 312 5.2 Bulk Richardson number

313 Since sonic anemometers are not commonly used in wind resource assessment, an alternative method to estimate the atmospheric stability is Bulk Richardson number. It is based on mean wind speed at height  $z$  and mean virtual potential temperature difference between air at the reference height ( $z$ ) and surface temperature.

316 The calculation of the Bulk–Richardson number is, in the present study, not straightforward because of the lack of reliable sensors at the surface. The lower air temperature is measured at 2 m in MP5 mast. Ideally, the temperature difference at the air–surface interface is required (Kaimal and Finnigan, 1994) for stability analysis. However, because of the lack of surface temperature, 2 m height air temperature has been chosen as representative. Observations of 118 m wind speed and 113 m air temperature have been used in conjunction with 2 m air temperature to estimate  $Ri_b$ .

322 ~~As in the work that is presented in some measurement campaigns, there are no~~ The MP5 mast has not measurements of surface temperature or near the ground. Some authors in these circumstances either extrapolate the values to the surface ( $z=0$ ) (Machefaux et al., 2016) or perform the calculation directly between the available temperature levels (Martin et al., 2016; Ruisi and Bossanyi, 2019; Zhan et al., 2020). To analyze how the choice of measurement heights may influence resulting  $Ri_b$  stability distributions the  $Ri_b$  has also been calculated using 38 m air temperature instead 2 m.

Comentario [ECN42]: Answer RC2 Technical corrections.

328 The values of the Bulk-Richardson number have been obtained over a period of 10 minutes, i.e. the same period used for calculation of the Obukhov length.

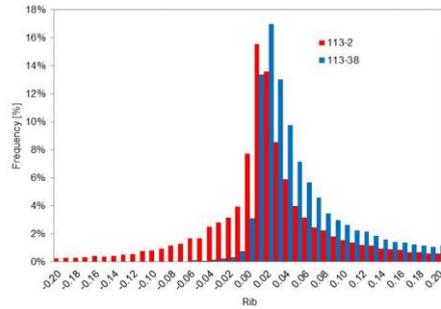

Comentario [ECN43]: Answer RC1 specific comments.

330 Figure 11 shows the distribution for the bulk Richardson number method. The lower measurement level is varied between 2 and 38 m. Using the 38 m level, it is observed that according to the classification in Table 2, unstable cases practically disappear. This is not physically possible and does not occur in the classification obtained by the sonic method (see Fig. 4). So in this case, the results obtained using the 38 m temperature sensor as a representative surface level does not give us any reliable information. Small temperature differences highly affect the result of the Richardson number method and therefore it is greatly affected by deviations in the measurement of this variable.

Comentario [ECN44]: Answer RC2 Technical corrections.

336 The MP5 temperature sensors have an accuracy of 0.3 °C and the mean temperature difference in the period  
 337 analyzed between the level of 38 m and that of 113 m has been 0.7 °C so the uncertainty of the measurement is of  
 338 the same order as the measurement itself.

339 The selection of temperature measurement heights has a great effect on the bulk Richardson number method,  
 340 both in the exactitude and in the applicability of the method. To reduce uncertainties the measurements should be  
 341 made either with differential temperature sensors or with calibrated sensors and a sufficient vertical separation in  
 342 order to reduce the influence of inaccuracies in the temperature measurements (Baker and Bowen, 1989; Brower,  
 343 2012).

344  
 345 **Figure 11 Probability distribution of  $Ri_b$  measured between 2 m and 113 (red one) and between 38 and 113 m (blue lines).**  
 346 **Only concurrent time steps between July 2014 and June 2015 are included.**

347  
 348 Figure 12 shows the distribution of atmospheric stability against wind speed. On the left side atmospheric  
 349 stability is directly classified with the  $Ri_b$  obtained with observations of 118 m wind speed, 113 m air temperature  
 350 and 2 m air temperature, this last temperature sensor has been chosen as representative of surface temperature. The  
 351 seven stability classes propose in Table 2 are reduced to five combining: weakly unstable and -stable classes with  
 352 unstable and -stable classes. Table 4 shows the classification used. On the right side atmospheric stability is  
 353 classified according to the stability parameter  $\zeta = z/L$  obtained with  $Ri_b$  and Eq. (3(3)) and according to stability  
 354 classification proposed in Table 3. The nine stability classes propose in Table 1 are reduced to five combining:  
 355 weakly un/stable classes with un/stable classes; and very un/stable with extremely un/stable.

356 **Table 4 According to Table 2 a reduced five stability classes.**

Stability Class	Stability parameter $Ri_b$
<u>Very unstable</u>	<u><math>Ri_b &lt; -0.023</math></u>
<u>Unstable</u>	<u><math>-0.023 &lt; Ri_b &lt; -0.0036</math></u>
<u>Neutral</u>	<u><math>-0.0036 &lt; Ri_b &lt; 0.0072</math></u>
<u>Stable</u>	<u><math>0.0072 &lt; Ri_b &lt; 0.084</math></u>
<u>Very stable</u>	<u><math>Ri_b &gt; 0.084</math></u>

358  
 359 Both distributions show a differentiated behavior with fewer “very” unstable and -stable situations and a greater  
 360 number of neutral observations in the case of the classification with  $\zeta$  (on the right side of Fig. 12).

363

364 **5.3 Comparison of stability methods: sonic versus bulk method**

365 Comparing the distribution of atmospheric stability against wind speed based on sonic method (Fig. 5) with the  
366 results obtained based on  $Ri_b$  method (Fig. 12); it is observed that there are important differences between them.

367 [Table 3](#) presents a frequency of occurrence of stability classes with concurrent data using different  
368 methods. This quantitative comparison shows that taking the sonic method as benchmark, it is observed that the bulk  
369 method when the Businger and Dyer functions are used to estimate the stability parameter  $\zeta = z/L$  over predict the  
370 percentage of neutral and stable conditions to the detriment of very unstable and stable situations, probably due to  
371 similar air temperature values at 113 an 2 m. On the other hand, classification directly with Rib according to Mohan  
372 classification over predict too the stable situations at the cost of under predicting the unstable ones. As is explained  
373 in some references (Bardal et al., 2018; Sathé et al., 2011), stability characterization with  $Ri_b$  have several weak  
374 points: in one hand  $Ri_b$  method is sensitive to temperature measurements and uncertainty in L estimation increases  
375 as the temperature difference is reduced. Besides, other source of uncertainty comes from the definition of the  
376 surface temperature. In the other hand Businger and Dyer functions have some limitations and as [Bardal et al.](#)  
377 [propose in](#) (Bardal et al., 2018) [propose](#) the use of more advanced methods for relating the  $Ri_b$  to ~~de the~~ z/L  
378 parameter might improve the results.

Comentario [ECN51]: Answer RC2 Technical corrections.

379 Besides these methodological reasons there are some physical causes of the differences found. One of these is  
380 that Richardson bulk number represents a bulk average stability value instead a local measurement like the sonic  
381 method.

Comentario [ECN52]: Answer RC2 Technical corrections.

382

383 **6. Conclusions**

384 In this work, a detailed data analysis focused on how to estimate atmospheric stability in a site with complex terrain  
385 was presented. The Obukhov parameter  $\zeta = z/L$ , which can be measured locally with the use of a sonic anemometer,  
386 and bulk Richardson number have been studied. The methods are examined considering their theoretical  
387 background, implementation complexity, instrumentation requirements, and practical use in connection with wind  
388 energy applications.

389 It is shown that the resulting stability depends on which method is chosen. The sonic method is ~~taking taken~~ as  
390 benchmark because is the only way of measuring local stability without the use of empirical functions or theoretical  
391 assumptions. However this method requires working with accurate high frequency data, rotating the measurements  
392 to align the coordinate system to the mean wind vector, which is reported to require special attention in complex  
393 terrain to guarantee that the mean streamline plane will be parallel to the terrain surface; to finally obtain turbulent  
394 fluxes using the eddy covariance technique.

**Comentario [ECN53]:** Answer RC2  
Technical corrections.

395 According to the stability parameter  $\zeta = z/L$  obtained with the three sonic anemometer installed in MP5 mast.  
396 For the three heights, the stable situations are slightly higher than the unstable ones and there is an increase of  
397 neutral and stable conditions with increasing wind speeds. There is a significant dependence of stability distributions  
398 with height. At higher levels, the stability distributions are broader and there are more frequent cases with very large  
399 and extreme stability.

400 The seasonal and diurnal cycle is identified, in the winter and during the hours between 17h to 8h stable side  
401 dominates, while between April to August and between 9h to 15h unstable conditions are found to be more frequent.  
402 Winds from the predominant northwest direction (330°-350°) produce more unstable conditions than the others  
403 sectors.

404 For the three heights, and in the two predominant sectors, is observed that in unstable situations the ground  
405 surface is warmer than the air above so there is a positive heat flux that causes more turbulence. This results in a  
406 convective, well-mixed, surface layer with small vertical gradients. On the other hand, lower turbulence and high  
407 shear wind profiles are associated to stable situations where turbulence is reduced due to a negative vertical heat  
408 flux.

409 As alternative to characterize stability, the bulk Richardson number is explored, it requires the minimum level of  
410 instrumentation, mean wind speed at height  $z$  and mean virtual potential temperature difference between air at the  
411 reference height ( $z$ ) and surface temperature. The bulk Richardson number can be used directly to ~~classified~~ classify  
412 the atmospheric stability or it can be transform into  $\zeta = z/L$  by Businger and Dyer functions.

**Comentario [ECN54]:** Answer RC2  
Technical corrections.

413 On MP5 there is not a surface temperature sensor so 2 m high air temperature sensor has been chosen as  
414 representative, moreover to analyze how the choice of measurement heights may influence resulting  $Ri_b$  stability  
415 distributions, it has also been calculated using 38 m air temperature sensor instead 2 m. This configuration does not  
416 give us any reliable information, it could be due temperature sensors on MP5 have an accuracy of 0.3°C and the  
417 mean temperature difference in the period analyzed between the level of 38 m and that of 113 m has been 0.7 °C so  
418 the uncertainty of the measurement is of the same order as the measurement itself. The  $Ri_b$  number relies on smaller  
419 temperature differences for estimation of the mean gradient and its accuracy is therefore dependent on the sensor  
420 precision, calibration and measurement heights. The following recommendations are provided to obtain consistent  
421 results with bulk Richardson method: use high precision temperature sensors; calibrate all the temperature sensors at  
422 the same time; calibrate the temperature sensors in the operational range to guarantee better calibration in the  
423 temperatures of interest and have a reference temperature sensor below 2 m, as close to the ground as possible.

**Comentario [ECN55]:** Answer RC1  
specific comments and RC2 General  
comments.

424 On the other hand, the stability classification obtained using directly the  $Ri_b$  values shows a differentiated  
425 behavior than that estimated according to the stability parameter  $\zeta = z/L$  obtained with  $Ri_b$  and Businger and Dyer  
426 functions. It could be by the different classification employed in both characterization (Mohan vs Sorbjan &  
427 Grachev) and/or by the Businger and Dyer functions.

428 In summary the sonic method is more costly and complex but, in this study, it shows results in accordance with  
429 the general atmospheric boundary layer knowledge, so we recommend it at as first option to obtain a local  
430 measurement of atmospheric stability that can be associated to a certain height above the ground. –For the Bulk  
431 Richardson number, based in the references read, there ~~isn't is no~~ a standard methodology for characterizing  
432 atmospheric stability using this method and there are many different approximations. Furthermore, empirical  
433 relations to relate  $Ri_b$  to  $\zeta = z/L$  are obtained either for offshore sites or for non-complex sites, so there is a need for  
434 observational studies on complex terrain to increase under-standing of how estimate atmospheric stability accurately  
435 with Bulk Richardson number.
