5 **Abstract.** Wind turbines in a wind farm extract energy from the atmospheric flow and convert it into electricity, resulting in a localized momentum deficit in the wake that reduces energy availability for downwind turbines. Atmospheric momentum convergence from above, below and sides into the wakes replenish the lost momentum, at least partially, so that turbines deep inside a wind farm can continue to function. In this study, we explore recovery processes in a hypothetical offshore wind farm with particular emphasis on comparing the spatial patterns and magnitudes of horizontal and vertical recovery processes and understanding the role of mesoscale processes in momentum recovery in wind farms. For this purpose, we use the Weather Research and Forecasting (WRF) model, a state-of-the-art mesoscale model equipped with a wind turbine parameterization, to simulate a hypothetical large offshore wind farm with different wind turbine spacings under realistic initial and boundary conditions. Results show that vertical turbulent transport of momentum from aloft is the main contributor to recovery in wind farms except in cases with strong background winds and high inter-turbine spacing where horizontal advective momentum transport can also contribute equally. Vertical recovery shows a systematic dependence on wind speed and wind farm density that can be quantified using low-order empirical equations. Wind farms significantly alter the mesoscale flow patterns, especially for densely packed wind farms under high wind speed conditions. In these cases, the mesoscale circulations created by the wind farms can transport high momentum air from aloft into the atmospheric boundary layer (ABL) and thus aid in recovery in wind farms. This is a novel study that is one of the first to look at wind farm replenishment processes under realistic meteorological conditions including the role of mesoscale processes. Overall, this study significantly advances our understanding of recovery processes in wind farms and wind farm-ABL interactions.

1 Introduction

Wind power is one of the most actively growing renewable energy sources around the world with increasing emphasis on offshore wind (IRENA, 2019). A wind turbine harvests kinetic energy from the wind to produce electricity. In doing so, it creates a momentum deficit in its wake, thereby reducing the kinetic energy availability for downwind turbines. This momentum deficit triggers convergence of momentum from outside the wakes through turbulent and mesoscale processes that partially replenish the lost momentum so that turbines deep inside a wind farm can continue to function (Akbar and Porté-Agel, 2014; Allaerts and Meyers, 2017; Baidya Roy and Traiteur, 2010; Cal et al., 2010; Calaf et al., 2010; Chamorro and

25

Porté-Agel, 2011; Cortina et al., 2016, 2020; Frandsen, 1992; Kinzel et al., 2012; Meyers and Meneveau, 2011; Possner and Caldeira, 2017; VerHulst and Meneveau, 2014; Yang et al., 2014).

A number of studies have quantitatively analyzed recovery processes for onshore wind farms using simulations from Large-
5 Eddy Simulation (LES) models. They show that for very large wind turbine arrays, the recovery occurs mostly due to vertical
momentum transport by turbulent eddies (Akbar and Porté-Agel, 2013; Cal et al., 2010; Cortina et al., 2016) whereas, for
isolated turbines, recovery is dominated by horizontal advective momentum transport by the mean flow (Cortina et al., 2016).
The importance of vertical transport is also confirmed by LES (Calaf et al., 2010) and wind tunnel (Cal et al., 2010) experiments
10 existing studies in this area have used LES models with relatively small simulation domains driven by periodic, no/free-slip
and other idealized boundary conditions. This prevents realistic interactions between the Atmospheric Boundary Layer (ABL)
and the free atmosphere and ignores mesoscale and larger scale processes that may contribute to the recovery in the real world.

The primary goal of this paper is to study recovery processes in offshore wind farms using numerical experiments with the
15 WRF model, a state-of-the-art mesoscale model equipped with a wind turbine parameterization. In particular, we want to (i)
comparatively explore the spatial patterns and magnitudes of horizontal and vertical recovery processes and (ii) understand
the role of mesoscale processes in momentum recovery in wind farms. Unlike earlier studies using LES models, the mesoscale
model domain is large and is driven by boundary conditions from observed data. This allows us to simulate a wide range of
phenomena, from turbulent to mesoscale and synoptic scale, including entrainment from the free atmosphere into the ABL.
20 To the best of our knowledge, this is the first study to explore the contribution of both turbulent and mesoscale processes in
momentum recovery in a wind farm under realistic conditions.

Our secondary goal is to explore the role of horizontal Turbulent Kinetic Energy (TKE) advection in recovery processes. The
WRF model allows users to activate the horizontal advection of TKE. Siedersleben et al. (2020) found that doing so leads to
25 significant underestimation of wind farm impacts on TKE. However, Archer et al. (2020) showed that the underestimation was
because of a bug in the WRF code. This issue has been rectified in the latest WRF release. In this paper we have used the bug-
free version to conduct sensitivity studies by deactivating the TKE advection process to evaluate the role of horizontal TKE
advection in the wind farm recovery.

30

2 Methodology

2.1 Model description

The numerical experiments are conducted using the Weather Research and Forecasting (WRF) model, a state-of-the-art mesoscale model that has been used for a wide range of applications. WRF solves the fully compressible, Eulerian, non-hydrostatic conservation equations for velocity, mass, energy and scalars. The vertical coordinate system is a terrain-following dry hydrostatic pressure coordinate system. The vertical grid is stretched with high resolution near the surface and coarse resolution aloft thereby allowing for better spatial resolution of ABL processes. The horizontal coordinate system uses a staggered Cartesian grid. WRF has numerous schemes to represent microphysics, cumulus convection, atmospheric radiative transfer, and ABL dynamics. The system is integrated using a Runge–Kutta 3rd order scheme. The model is capable of 3D variational data assimilation where boundary conditions are obtained from real world meteorological reanalyses data. Further details about the WRF model are available from Skamarock et al. (2008).

WRF is equipped with a subgrid-scale wind turbine parameterization that is capable of simulating the interactions between wind turbines and the atmosphere (Fitch et al., 2012; Fitch, 2016). In this parameterization, a wind turbine is treated as an elevated sink of momentum and source of turbulence, a concept first proposed by Baidya Roy et al. (2004). For this purpose, a sink term is added to the horizontal momentum equations and a source term is added to the Turbulent Kinetic Energy (TKE) equation. The magnitude of the source and sink terms are calculated using the thrust and power coefficients of the wind turbine.

2.2 Model configuration

The model simulation domain is a 1500 km × 1500 km box located deep in Arabian Sea, off the west coast of India (Fig. 1). It is discretized with 1 km grid spacing in the horizontal. The domain is intentionally kept larger than usual to ensure that wind farm wakes do not get reflected from the lateral boundaries. The fine resolution domain is nested within two coarser domains of size 3000 km × 3000 km and 4900 km × 4900 km that are discretized with 3 km and 9 km grid spacing, respectively. The domain goes up to 100 hPa in the vertical and is discretized with 61 levels using a stretched grid that has 7 levels within the lowest 150 m to better resolve wind turbine-ABL interactions.

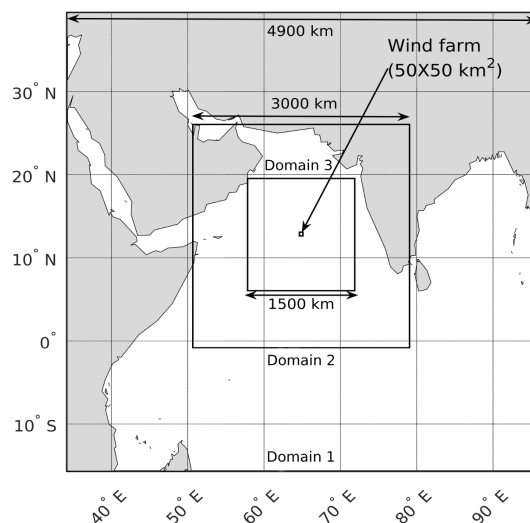

Figure 1: Model domain showing the three nested grids. The small rectangle in the centre shows the wind farm.

The atmospheric initial conditions and lateral boundary conditions were obtained from the National Centers for Environmental Prediction Final Operational Global Analyses dataset (NCEP, 2015). Microphysical processes are represented using the WRF single moment 6-class scheme (WSM6, Hong and Lim, 2006), radiative transfer is represented using the Goddard shortwave scheme (Chou and Suarez, 1999; Chou et al., 2001) for shortwave and the Rapid Radiative Transfer Model for General circulations models scheme (RRTMG, Iacono et al., 2008) for longwave. The new Eta Kain–Fritsch scheme (Kain, 2004) is used to represent cumulus convection in the coarsest grid while the finer grids resolve convection. The system is closed with the 1.5-order Mellor–Yamada–Nakanishi–Niino (MYNN) boundary layer scheme (Nakanishi and Niino, 2009) where TKE is prognosed while other second order moments are parameterized. The source term in the wind farm parameterization is added to the TKE prognostic equation.

For the numerical experiments, a hypothetical wind farm covering a 50 km × 50 km area is placed in the centre of the finest grid domain. The wind farm consists of wind turbines with 84 m hub-heights, 112 m rotor diameter (D), and rated 3.075 MW. The power curve of this turbine is shown in Fig. 2. The turbines are distributed uniformly within the wind farm with the following three different inter-turbine spacings: (I) 0.5 km (~5D) where 4 turbines are placed in each grid cell; (II) 1 km (~10D) where 1 turbine is placed in each grid cell; and (III) 2km (~20D) where 1 turbine is placed in each alternate grid cell.

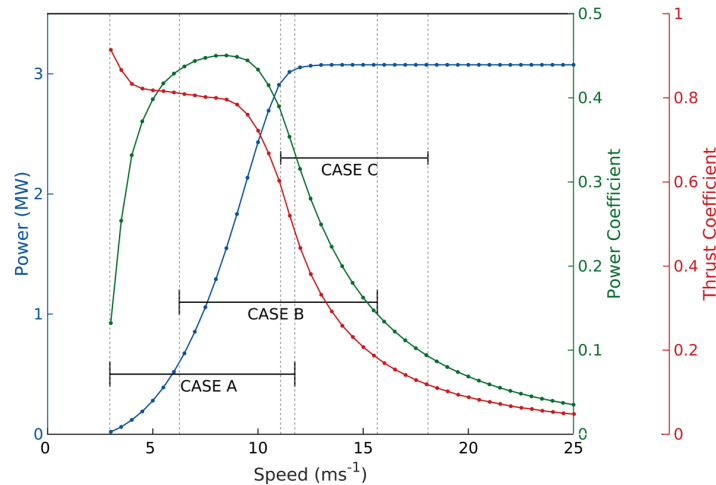

Figure 2: Power curve (blue), power coefficient (green) and thrust coefficient (red) of 3.075 MW Vestas turbine as a function of wind speed. The horizontal bars represent the wind speed ranges during the 3 cases simulated.

5 Based on the power curve, three time periods are chosen for our simulations to cover the whole range of wind speed at which the wind turbine is operational. The time periods are: (A) Jan 10 to 13, 2015 when the wind speed is in the range 2.9 to 11.75 ms^{-1} ; (B) June 10 to 13, 2015 when the wind speed is in the range 6.2 to 15.7 ms^{-1} ; and (C) July 10 to 13, 2015 when the wind speed is in the range 11 to 18 ms^{-1} (Fig. 2). The first days of simulations are considered as spin-up and model outputs for the remaining two days are analyzed for this study. In addition to the wind farm simulations (WF), a control simulation (CTRL)

10 where the wind turbine parameterization is switched off is also conducted for each of these time periods. These add up to 12 simulations including 3 CTRL simulations for 3 time periods and 9 experimental WF simulations for 3 inter-turbine spacings for 3 time periods.

The above 12 simulations are conducted using the latest bug-free WRF model (Archer et al., 2020) with the TKE horizontal advection switch turned ‘on’. This allows us to simulate realistic transport of TKE by both subgrid turbulent and grid-resolved mean flow. To explore the effect of horizontal TKE advection on replenishment, we repeat all the 12 simulations with the TKE advection switch turned ‘off’. In this case, TKE transport occurs only through vertical subgrid-scale transport processes.

2.3 Quantification of fluxes, recovery and momentum loss rate

20 2.3.1 Synoptic, mesoscale and turbulent fluxes

The synoptic and mesoscale fluxes are calculated using Avissar and Chen (1993). They posit that atmospheric variables can be partitioned into synoptic, mesoscale and microscale components. This approach has been used to study mesoscale

circulations driven by landscape heterogeneity (e.g., Li et al., 2011; Noppel and Fiedler, 2002; Zeng and Pielke, 1995). As per their formulation, a variable ϕ resolved by the model grid consists of a mesoscale perturbation ϕ' superimposed on a synoptic scale mean $\bar{\phi}$ and can be written as:

$$\phi(k, i, j) = \overline{\phi(k)} + \phi'(k, i, j), \quad (1)$$

5 where the overbar represents a horizontal average. Hence, the vertical synoptic scale kinematic flux of the zonal momentum (u) and meridional momentum (v) are given by:

$$\overline{UW}_{synop} = \overline{uw}, \quad (2)$$

$$\overline{VW}_{synop} = \overline{vw}, \quad (3)$$

10 respectively, and the vertical mesoscale kinematic flux of the zonal momentum (u) and the meridional momentum (v) are given by:

$$UW_{meso} = (u - \bar{u})(w - \bar{w}) \quad (4)$$

$$VW_{meso} = (v - \bar{v})(w - \bar{w}) \quad (5)$$

15 respectively. Here $u(k, i, j)$, $v(k, i, j)$ and $w(k, i, j)$ are grid resolved zonal, meridional and vertical velocities, respectively. The microscale kinematic flux of the zonal and meridional momentums are $u'w'(k, i, j)$ and $v'w'(k, i, j)$, which are calculated by the MYNN scheme.

As per the Avissar and Chen (1993) formulation, the mesoscale and microscale fluxes can be estimated at each model grid cell. However, the synoptic-scale fluxes can only be estimated at each vertical level because by definition they are horizontally averaged quantities. Hence, in this study, all fluxes are horizontally averaged so they can be compared to each other.

20 2.3.2 Horizontal and vertical recovery

Recovery terms are calculated from the kinematic advective and turbulent transport terms in the Reynolds-averaged Navier–Stokes' equation that (Stull, 2012) that give the contribution of advection and turbulence, respectively, to the momentum tendency. Horizontal recovery in the wind farms is calculated by taking the difference in advective momentum transport between the WF and CTRL cases as follows:

$$25 \text{ Horizontal Recovery} = \left[\left(-u \frac{\partial u}{\partial x} - v \frac{\partial u}{\partial y} \right) \hat{i} + \left(-u \frac{\partial v}{\partial x} - v \frac{\partial v}{\partial y} \right) \hat{j} \right]_{WF} - \left[\left(-u \frac{\partial u}{\partial x} - v \frac{\partial u}{\partial y} \right) \hat{i} + \left(-u \frac{\partial v}{\partial x} - v \frac{\partial v}{\partial y} \right) \hat{j} \right]_{CTRL}, \quad (6)$$

where, u and v are the hub-height wind speeds in the zonal (x) and meridional (y) directions, respectively. The gradients are calculated using central finite differencing method. For example, the advection of zonal wind u at a grid point (i,j) is calculated as:

$$\left(-u \frac{\partial u}{\partial x} - v \frac{\partial u}{\partial y} \right)_{(i,j)} = -u(i,j) \frac{u(i+1,j) - u(i-1,j)}{2\Delta x} - v(i,j) \frac{v(i,j+1) - v(i,j-1)}{2\Delta y}, \quad (7)$$

- 5 The advection of meridional wind (v) is calculated in a similar way. The vector difference in Eq. (6) is projected against the prominent wind direction from the CTRL case.

Vertical recovery is calculated by taking the difference in vertical turbulent transport between the WF and the CTRL cases as follows:

$$10 \text{ Vertical Recovery} = \left[-\left(\frac{\partial u'w'}{\partial z} \right) \hat{i} - \left(\frac{\partial v'w'}{\partial z} \right) \hat{j} \right]_{WF} - \left[-\left(\frac{\partial u'w'}{\partial z} \right) \hat{i} - \left(\frac{\partial v'w'}{\partial z} \right) \hat{j} \right]_{CTRL}, \quad (8)$$

where $u'w'$ and $v'w'$ are the vertical kinematic turbulent flux of the zonal and meridional momentums, respectively. These fluxes are calculated by the MYNN scheme at the model grid points. They are interpolated to the heights of 28 m and 140 m, the lower and upper wind turbine blade tip heights, respectively. The vertical gradient of the fluxes are then calculated between these two levels. For example, the vertical turbulent transport of zonal momentum is calculated as:

$$15 \frac{\partial u'w'}{\partial z} = \frac{u'w'|_{z=140m} - u'w'|_{z=28m}}{112}, \quad (9)$$

Vertical turbulent transport of meridional momentum is calculated in a similar way. In this approach we ignore the vertical transport of momentum by the large-scale vertical wind. This term is very small compared to the turbulent transport because large-scale vertical motion is typically close to zero in the ABL. The vector difference in Eq. (8) is projected against the prominent wind direction from the CTRL case.

20

2.3.3 Momentum loss rate

The momentum loss rate (ms^{-2}) is calculated as per Fitch et al. (2012):

$$\frac{\partial |V|}{\partial t} \Big|_{(k,i,j)} = - \frac{\frac{1}{2} N_t(i,j) C_T \{ |V(k,i,j)| \} |V(k,i,j)|^2 A(k,i,j)}{z(k+1,i,j) - z(k,i,j)}, \quad (10)$$

where, $V(k,i,j) = [u(k,i,j), v(k,i,j)]$ is the horizontal wind velocity (ms^{-1}), $N_t(i,j)$ = number of turbines per square

- 25 metre (m^{-2}) for the grid cell (i, j), C_T = turbine thrust coefficient which is dependent on V , $A(k,i,j)$ = cross-sectional rotor

area (m^2) and $z(k, i, j)$ = height (m) of level k . The momentum loss rate is projected along the prominent wind direction from the CTRL case for it to be consistent with the recovery terms.

3. Results

3.1 Power generation in the wind farms

5 The wind regime and the power generated by the wind farm experiments are shown in Fig. 3. Figure 3a shows the wind rose for CTRL case wind speeds over the wind farm area. For case A, 50% of winds are north-easterly. In contrast, the winds are mostly west-southwesterly for case B (84%) and C (100%), As discussed earlier, case A has the weakest wind speed while case C has the strongest wind speed.

10 **Table 1: Power generated (GW) by the wind farms. Wind farm efficiencies are given in parentheses.**

Cases	I	II	III
A	2.81 (31%)	1.60 (70%)	0.51 (90%)
B	8.68 (31%)	5.44 (78%)	1.64 (94%)
C	24.15 (81%)	7.65 (100%)	1.92 (100%)

In case I, 10000 wind turbines with 3.075 MW rating are placed 0.5 km apart over a 2500 km² area leading to a 30.75 GW installed capacity. Cases II and III have 2500 and 625 turbines spaced 1 km and 2 km apart leading to 7.687 GW and 1.921 GW installed capacities, respectively. The power generated by the wind farms are shown in Table 1. As expected, increasing
 15 wind speeds increase power generation with case A generating the least amount of power and case C the most. Sparsely packed wind farms produce less power because of the lower installed capacity but their efficiencies are higher because increased inter-turbine spacing reduces the wake effects. For example, the densely packed case A-I produces 2.81 GW of power while the sparsely packed case A-III produces 0.51 GW. However, case A-I operates at 31% efficiency while case A-III at 90% efficiency. Cases C-II and C-III are 100% efficient. This is because the high wind speed in case C and the low wake effects
 20 due to the high inter-turbine spacing ensures that the wind speed is always above the rated wind speed of 12 m s⁻¹ of the turbine (Fig. 2).

The spatial patterns of power generation (Fig. 3b) show that generation is the highest for the first few rows of turbines of the wind farms at the upwind edges in the direction of the dominant winds (Fig. 3b). The power production decreases inside the
 25 wind farm due to wake effects for all cases except C-II and C-III. As explained above, the high wind speed and low wake effects result in the turbines in these two cases always operating at the rated power.

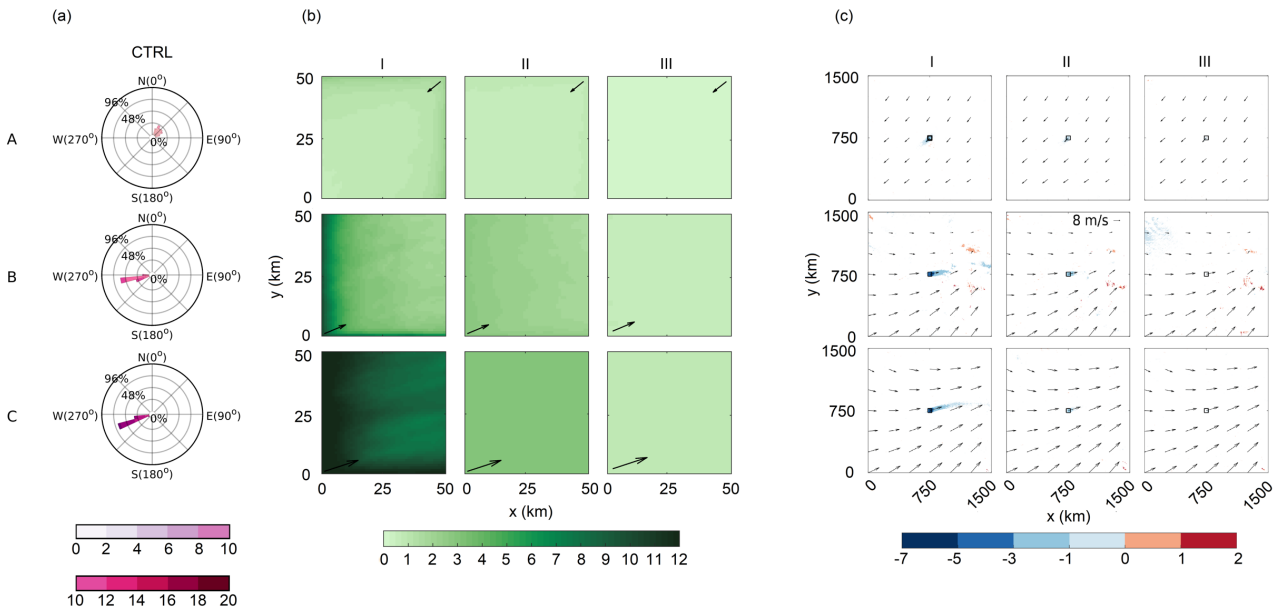

Figure 3: (a) Wind rose diagrams depicting hub-height wind speeds (ms^{-1}) over the wind farm area for the CTRL case, (b) averaged power (MW) generated in the WF cases, and (c) averaged difference in hub-height wind speed (ms^{-1}) (WF-CTRL) for (A) January, (B) June, and (C) July with (I) 0.5 km, (II) 1 km and (III) 2 km inter-turbine spacings. In Fig. 3 (b), the plot depicts the wind farm only and the black arrow shows the prominent wind direction. In Fig. 3 (c), only the statistically significant results ($p < 0.01$) are shown. The vectors represent the wind in the corresponding CTRL case.

3.2 Wind farm wakes

A comparison of the wakes from wind farms for the different experiments are shown in Fig. 3c. The wind roses (Fig. 3a) for the three simulation days for the three CTRL cases confirm that the wind speeds are in the operating range of the wind turbine (Fig. 2) during the study periods. Case A has the weakest wind speeds while case C is the strongest. The winds are north-easterly in case A but west-southwesterly in the other two cases.

The wind farm wakes are represented by the differences in wind speeds averaged over the rotor depth (28 m – 140 m) between the experiment and control cases (WF-CTRL) that are statistically significant at $p < 0.01$ using the non-parametric Wilcoxon Sign Rank Test (Fig. 3c). Several interesting features of the wakes can be observed from this figure. First, the wakes follow the predominant wind directions resulting in wakes towards the southwest for case A and east-northeast in cases B and C. Second, the wake length increases with the increasing wind speeds. For example, the wake length increases from 80 km to 223 km and further to 521 km with the increasing wind speed for cases A-I, B-I and C-I, respectively. The same pattern is observed for cases II. Third, the wake length decreases with increasing inter-turbine spacing. For example, the wind farm wake length decreases from 224 km to 85 km and further to 0 km for cases B-I, B-II and B-III, respectively. A similar pattern is observed for the other cases. Fourth, almost no discernible wind farm wake is observed for sparsely packed wind farms with 2 km spacing in case III.

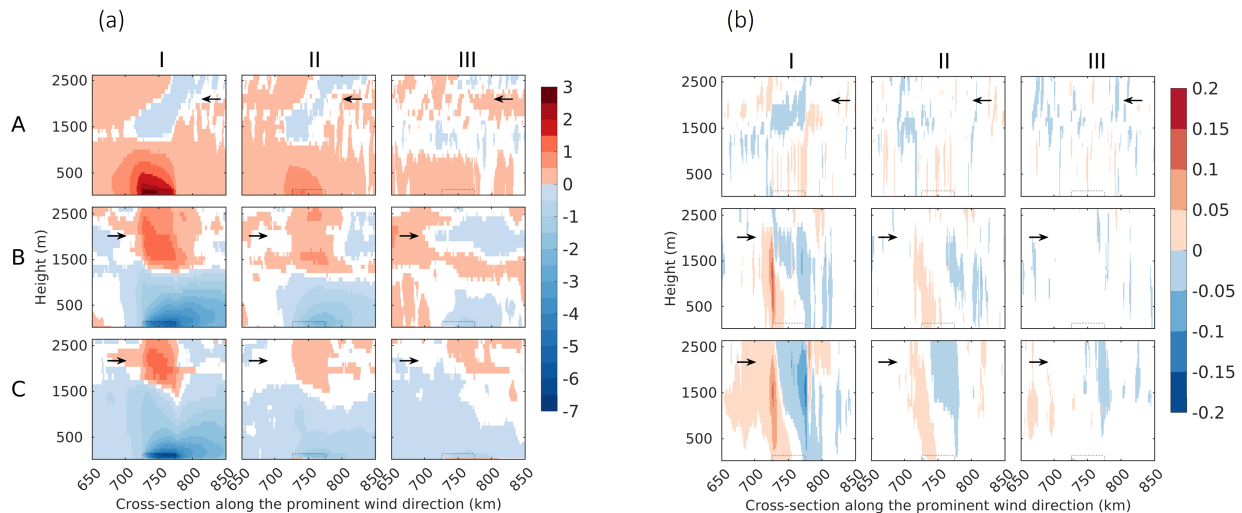

The wakes are extremely strong and long in B-I and C-I. In these cases, the wind speeds are strong, and the wind farms are densely packed. For example, in C-I, the wake is ~521 km long with an average wind speed reduction of 7% at hub-height can be seen behind the wind farm in the direction of the wind flow. Immediately downwind of the wind farm (~50 km), the average hub-height wind speed reduction is 15%. These values are larger than the other studies. For example, Fitch et al. (2012) reported a 11% decay 11 km behind a 10 X10 km modeled wind farm. Christiansen and Hasager (2005) also observed an 8–9% reduction in the wind speed, immediately downstream of the Horns Rev and Nysted offshore wind farms. The wind farms in these studies are much smaller in size than the wind farm simulated in our work.

3.3 Circulation patterns around offshore wind farms

Figure 4a shows the difference (WF-CTRL) in horizontal wind velocity component on a vertical cross-section along the prominent wind direction. The cross-sections are averaged over a 30 km wide band around a line running through the center of the wind farm. Figure 4b shows the same but for vertical velocity. For clarity, we focus on a region 100 km up and downwind of the wind farms depicted by the dashed box instead of the entire 1500 km span of the domain. One important thing to note here is that in case A, unlike cases B and C, a positive value in the difference plot indicates a velocity deficit because the prominent wind is towards the negative x-direction. Four major features are observed from these plots. First, there is a strong reduction in the horizontal wind speed up to 7 ms^{-1} within the wind farm due to extraction of kinetic energy by the wind turbines. Second, the wind farm wakes are clearly visible as strong wind speed deficits up to 5 ms^{-1} downwind of the wind farms. The wind farm wakes can spread vertically up to the top of the ABL at around 1–1.5 km. These effects are stronger for higher wind speeds and higher wind farm density.

The third feature is the reduction in wind speed upwind of the wind farms while the fourth is the increase in horizontal wind speed above the wind farm that are visible in all the simulations. These two features occur because the wind farm acts as a barrier to the flow. The incoming wind slows down as it approaches the wind farm causing the observed upwind stilling. A part of the incoming flow rises above the wind farm at the upwind edge. The vertical displacement is quite deep, even going much higher than the ABL top. The lifted flow then descends near the downwind edge of the wind farm. This pattern is stronger for higher wind speeds and higher wind farm density. Similar patterns of upwind stilling and lifting have also been observed by other studies (Bleeg et al., 2018; Porté-Agel et al., 2020).

5 **Figure 4: (a) Difference in horizontal wind speed (ms^{-1}) (WF-CTRL) and, (b) Difference in vertical wind velocity (ms^{-1}) (WF-CTRL) on a vertical cross-section along the predominant wind direction for case: (A) January, (B) June, and (C) July with (I) 0.5 km, (II) 1 km, and (III) 2 km turbine spacings. Only the statistically significant results ($p < 0.01$) are shown here. The black dashed box depicts the wind farm cross-section. The arrows represent the predominant wind direction.**

Corroborating evidence of the lifting is visible in the vertical cross-section of vertical wind velocity difference, especially for cases A, B and C, I and II (Fig. 4b). These plots show an upward motion at the upwind edge of the wind farm and a downward motion beyond that. In case C-I, there is widespread descending motion over almost the entire wind farm. There is no statistically significant signal in vertical velocity for the sparsely packed wind farms in cases III. The lack of a strong signal in the vertical velocity field is not unusual because vertical velocities in mesoscale flow are notoriously hard to simulate (Weaver, 2009).

10

3.4 Effect of wind farms on synoptic, meso and micro-scale momentum fluxes

Figure 5 compares the vertical profiles of the synoptic, meso and micro-scale vertical momentum fluxes for the WF cases with the CTRL case. The figure shows the difference (WF-CTRL) in the flux profiles between the experimental and the corresponding control cases horizontally averaged over the wind farm area for the 2-day simulation period. Results show that the difference in synoptic scale flux profiles is negligible. This indicates that the wind farms do not affect synoptic scale flow and momentum transport in a significant way.

15

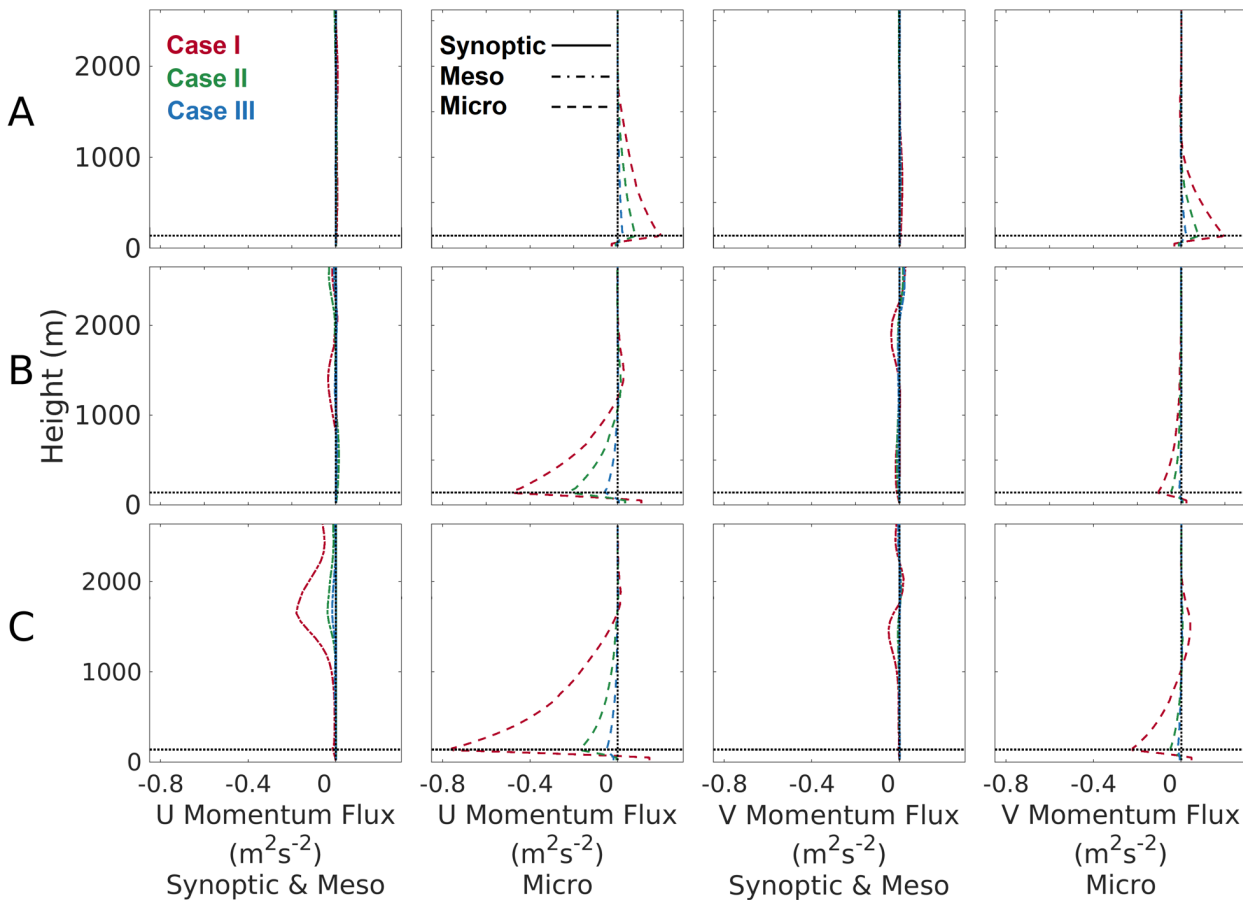

Figure 5: Difference (WF-CTRL) in vertical profiles of vertical synoptic, mesoscale, and microscale fluxes averaged over the wind farm for the simulation period for (A) January, (B) June and (C) July. Horizontal black dotted line shows the height of the upper tip of the wind turbine rotor.

- 5 Wind farms affect vertical mesoscale momentum fluxes only in case C-I. In this case, the difference in flux is negative indicating that the mesoscale flow generated by the wind farm leads to a downward transport of momentum into the ABL from aloft. Because the predominant wind direction is towards the east, the signal is observed only in the u-momentum flux but not in the v-momentum flux. The magnitude of the downward mesoscale momentum transport is smaller but of the same order of magnitude as the turbulent transport term. It is possible that this mesoscale momentum transport aids in the wind farm recovery
- 10 by making more momentum available for downward mixing by turbulence. The other cases do not show any significant mesoscale transport even though they create mesoscale perturbations in the flow (Fig. 4). This is because, the mesoscale fluxes associated with the updrafts and downdrafts are confined to narrow bands that disappear upon spatial averaging. Hence, the mesoscale perturbation in these cases do not lead to a strong signal in vertical mesoscale fluxes.

Wind farms strongly affect the microscale fluxes. In this figure, a positive (negative) flux difference indicates an upward (downward) transport compared to the control except for case A where the opposite is true because the horizontal wind is towards the negative x-direction. The results show that subgrid-scale turbulent eddies transport momentum to the turbine hub-height level from above and below the rotors. The magnitudes of the microscale fluxes are much larger than the mesoscale fluxes indicating that turbulent transport is the primary mode of vertical replenishment in wind farms.

The magnitudes of the fluxes increase with increasing wind speed and wind farm density. Case A with the weakest wind has the lowest fluxes while case C with the strongest wind has the highest fluxes. Case I with the densely packed wind farm has the highest flux while case III with the sparsely packed wind farm has the lowest flux. The relative magnitudes of the u and v momentum fluxes depend on their wind directions. In case A, where the winds are northeasterly with u and v components of similar magnitudes, the corresponding fluxes also have similar magnitudes. On the other hand, in cases B and C, where the winds are west-southwesterly with stronger u components than v , the u momentum flux is much higher than the v momentum flux.

3.5 Recovery in the wind farm

3.5.1 Quantitative assessment of vertical and horizontal recovery

Figure 6a and 6b show the spatial patterns of vertical and horizontal recoveries, respectively, over the wind farm. The arrows show the dominant direction of the wind flow at turbine hub-height level. It can be seen that the vertical recovery occurs all over the wind farm, but it is the weakest at the upwind edges. The magnitude of vertical recovery is stronger for stronger wind speeds and higher wind turbine density.

The horizontal recovery has an interesting spatial pattern. For cases with high turbine density and strong wind speed like A-I, B-I and C-I, horizontal recovery occurs mostly at the upwind. In these cases, power production is maximum at the upwind edges (Fig. 3b) creating a strong localized gradient in momentum. Because the horizontal wind speeds are strong, horizontal advection can replenish the momentum deficit faster than vertical turbulent diffusion. For cases with low turbine density like A-III, B-III and C-III, horizontal recovery also occurs throughout the wind farm as bands perpendicular to the predominant wind direction. In these sparsely packed cases, the wind turbines are placed in alternate grid cells. Horizontal recovery only affects the grid cells containing the wind turbines, resulting in the banded pattern with peak magnitudes similar to that of vertical recovery. The vertical and horizontal recovery patterns from densely packed cases C-I and B-I are similar to the findings of Cortina et al. (2020), where finite-sized high-density wind farms are simulated using an LES model under neutral stability conditions.

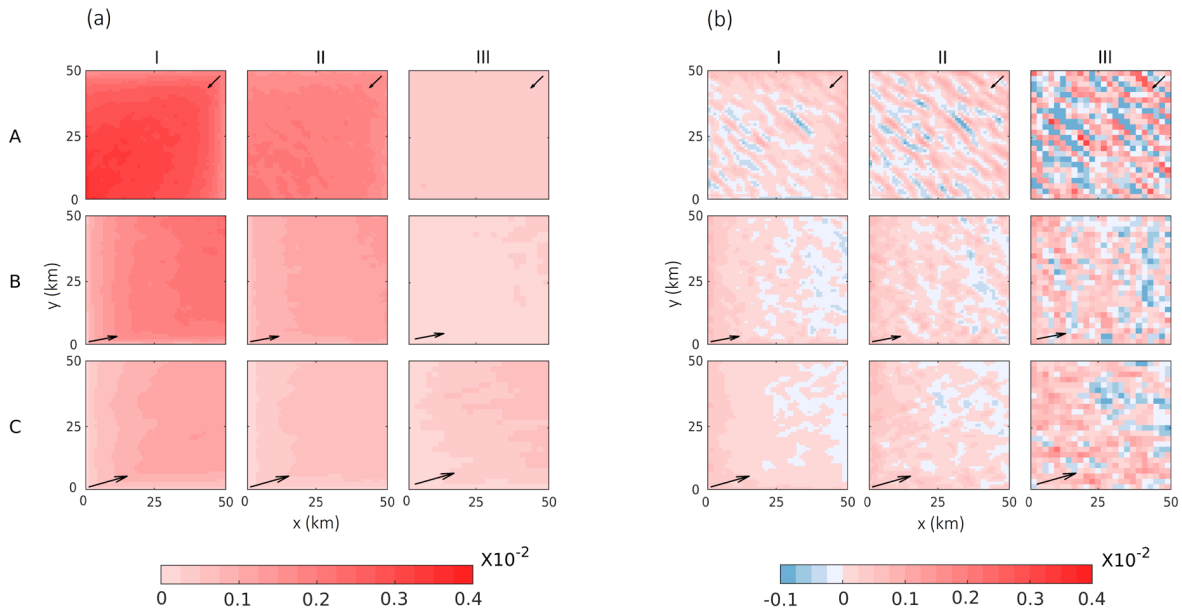

Figure 6: (a) Vertical recovery (normalized by power) and (b) Horizontal recovery (normalized by power) for case (A) January, (B) June, and (C) July with (I) 0.5 km, (II) 1 km, and (III) 2 km turbine spacings over the wind farms. Black arrows (scaled to the magnitude of averaged wind speed) show the prominent wind direction from the CTRL case.

5

Table 2 shows the averaged momentum loss rate, vertical recovery and horizontal recovery over the wind farms. The momentum loss rate over the wind farm is calculated as described in section 2.3.3. As per Eq. (10), momentum loss rate is directly proportional to three main components: (i) the number of wind turbines per square metre, (ii) the thrust coefficient of the turbines that is a function of horizontal velocity and (iii) the square of horizontal velocity. As expected, the magnitude of momentum loss rate decreases with decreasing turbine density. The relationship between momentum loss rate and wind speed is complex. In case I, the momentum loss rate increases with increase in wind speed. However, for case II and III, the momentum loss rate first increases from case A to B and then, decreases from case B to C. In these cases, for lower wind speed range in cases A and B, the reduction in thrust coefficient is relatively small (Fig. 2). Hence, the wind speed drives the momentum loss rate and with increase in wind speed, momentum loss rate increases. However, as the wind speed further increases to the level of case C, the drop in thrust coefficient is large. In this case, the drop in thrust coefficient dominates the momentum loss rate. Due to reduction in thrust coefficient, momentum loss rate decreases. Overall, the momentum loss rate over the wind farm is dependent on a complex interplay between the three earlier mentioned terms.

Vertical recovery follows the same pattern with respect to wind speed and inter-turbine spacing (Table 1) as momentum loss rate. This is because vertical recovery is a linear function of the momentum loss rate's magnitude (Fig. 7a). Horizontal recovery increases with increase in wind speed and decrease in inter-turbine spacing for all the cases. As per Eq. (6), the horizontal

recovery is directly proportional to (i) the wind speed upstream of the wind turbine and (ii) spatial gradient of wind speeds across a wind turbine. Therefore, as wind speed increases from case A to C, the horizontal recovery increases. Similarly, as the inter-turbine spacing increases from case I to III, the spatial gradient of wind speed decreases and hence horizontal recovery decreases.

5

The wind farm momentum extracted by the turbines is largely replenished by vertical recovery. The replenishment by vertical recovery is in the 47.2% to 70.8% range and it increases with decreasing turbine density similar to the findings of Cortina et al. (2017). Horizontal recovery plays a relatively small role, replenishing about 6.6% to 31.6% of momentum loss. Overall, the total replenishment of momentum in the wind farms lies in between 77.3% (case III) to 79% (case II). This indicates that the two recovery terms considered here are not able to completely replenish the momentum loss.

10

Table 2: Momentum loss rate ($\times 10^{-3}$), ms^{-2} , vertical recovery ($\times 10^{-3}$), ms^{-2} , and horizontal recovery ($\times 10^{-3}$), ms^{-2} averaged over the wind farm and the simulation period. The numbers in the parenthesis give the percentage recovery with respect to the corresponding momentum loss rate.

Cases	I			II			III		
	Mom. Loss Rate	Vert. Recovery	Horiz. Recovery	Mom. Loss Rate	Vert. Recovery	Horiz. Recovery	Mom. Loss Rate	Vert. Recovery	Horiz. Recovery
A	-3.93	2.78 (70.6%)	0.26 (6.6%)	-1.62	1.15 (70.8%)	0.20 (12.3%)	-0.47	0.32 (67.6%)	0.04 (9.1%)
B	-7.61	5.37 (70.5%)	0.58 (7.6%)	-3.27	2.22 (67.8%)	0.35 (10.7%)	-0.86	0.55 (63.6%)	0.11 (12.7%)
C	-12.32	8.39 (68.1%)	1.17 (9.5%)	-2.59	1.52 (58.7%)	0.43 (16.5%)	-0.61	0.29 (47.2%)	0.19 (31.6%)

15

3.5.2 Characterization of vertical recovery

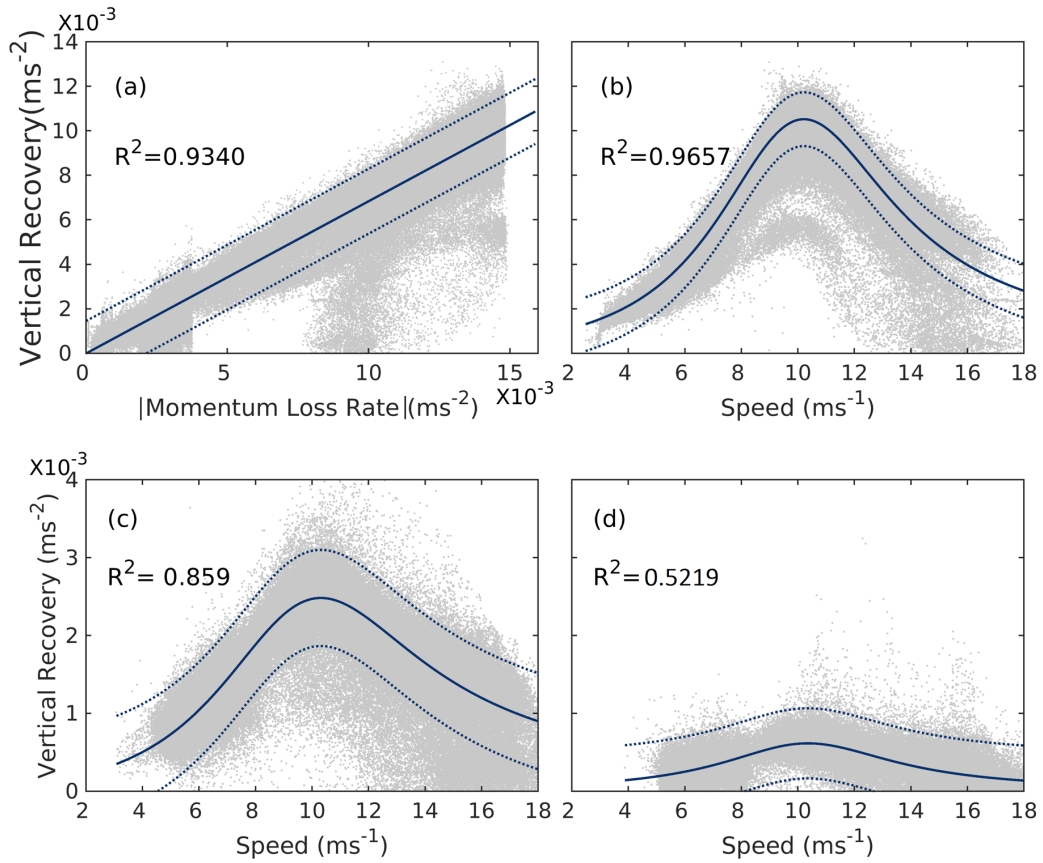

The results above show that replenishment in wind farms is primarily due to vertical recovery. Therefore, in this section, we further analyze vertical recovery by characterizing its relationship with momentum deficit and upwind wind speeds (Fig. 7). We also develop empirical equations to quantify the relationship.

20

Vertical recovery varies in direct proportion to the momentum extracted by the turbines. This is evident from Fig. 7 (a), where vertical recovery is plotted with respect to momentum loss rate. Figures 7 (b), (c) and (d) depict the scatter plot of vertical recovery with respect to upwind wind speeds for the three different wind turbine densities. These plots show that vertical recovery increases with wind speed until the rated wind speed of the wind turbine is reached. Beyond the rated wind speed,

vertical recovery starts decreasing. This is because the momentum deficit increases until the rated wind speed and then decreases.

5 **Figure 7: Scatter plot of vertical replenishment with (a) absolute momentum loss rate for all cases; and upwind wind speed for (b) case A-I, B-I and C-I, (c) case A-II, B-II and C-II and (d) case A-III, B-III and C-III. The solid blue line indicates the best fit and dashed blue line indicates the 99% prediction intervals.**

The empirical relationships for vertical recovery as a function of momentum loss rate and wind speed and are:

$$1) \quad y = 0.6841|x_1| - 0.0000103, \quad (11)$$

$$10 \quad 2) \quad y = \frac{0.009567x_2 + 0.06145}{x_2^2 - 19.35x_2 + 108.7}, \quad d=0.5 \text{ km} \quad (12)$$

$$3) \quad y = \frac{0.004154x_2 + 0.008504}{x_2^2 - 18.95x_2 + 109.8}, \quad d=1 \text{ km} \quad (13)$$

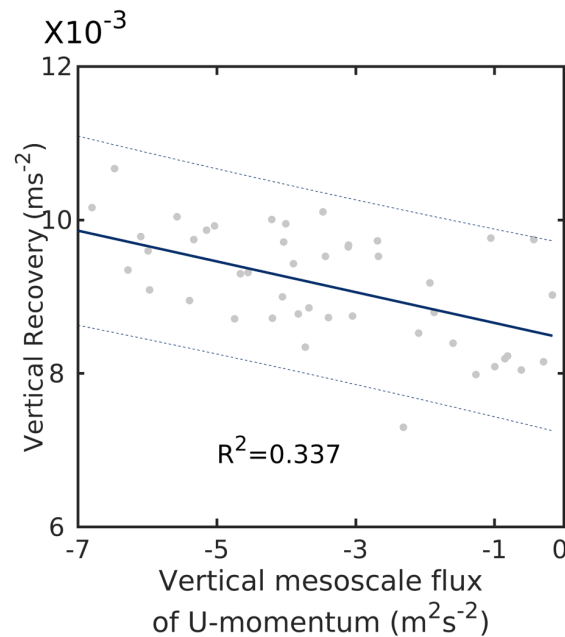

$$4) \quad y = \frac{0.0001853x_2 + 0.006901}{x_2^2 - 20.4x_2 + 118.4}, \quad d = 2 \text{ km} \quad (14)$$

Where, y is vertical recovery (ms^{-2}), x_1 is momentum loss rate (ms^{-2}), x_2 is upwind hub-height wind speed (ms^{-1}) and d is the inter-turbine spacing.

5

3.6 Dependence of vertical recovery on mesoscale fluxes

Section 3.3 shows that only case C-I generates mesoscale fluxes of the same order of magnitude as turbulent fluxes. It is likely that downward transport of momentum by mesoscale eddies in this case can make more momentum available for turbulent eddies and thereby aid in recovery. To further investigate this issue, we look at the relationship between vertical recovery and the vertical mesoscale flux of u momentum (Fig. 8). The vertical mesoscale flux of the horizontal momentum is calculated as per the formulation given in section 2.3.2 and then integrated between 1000–2500 m levels. It can be seen that as the mesoscale fluxes of horizontal u momentum increases in magnitude the vertical recovery increases. This suggests a direct dependence of vertical recovery on mesoscale fluxes.

15 **Figure 8: Scatter plot of averaged vertical recovery (at hub-height) on averaged vertical mesoscale flux of u momentum (integrated between 1000–2500m) for case C-I. The values are averaged over the wind farm. The solid blue line shows the best-fit and the dashed blue lines show the 95% prediction intervals.**

3.7 Effect of TKE advection on recovery processes

Results show that the effect of horizontal advection of TKE on recovery is minimal. As expected, turning off horizontal TKE advection leads to changes in the vertical profile of TKE because TKE transport occurs only through vertical subgrid-scale turbulence. This leads to statistically significant changes in vertical recovery but the magnitude of the changes are small, up to 5%. There is no significant effect on horizontal recovery. The spatial pattern of recovery remains the same as in the experiments where horizontal TKE advection is activated.

4. Conclusions and Discussions

Turbines in a wind farm extract momentum from the flow and converts that to electricity. This study quantitatively explores the recovery processes through which the lost momentum is replenished so that wind farm can continue to function. For this purpose, a mesoscale model is used to simulate recovery processes in a hypothetical offshore wind farm. The model is equipped with a wind turbine parameterization and is driven by realistic initial and boundary conditions numerical experiments. The experiments quantify the recovery processes under different wind speeds and wind turbine spacings. The main conclusions of the study are as follows:

- Power generation in wind farms increases with increasing wind speeds with maxima at the upwind edges. The efficiency of wind farms increases with increasing inter-turbine spacings due to reduction in wake effects. In some cases with strong wind speeds, a wind farm with a 2 km spacing can operate at 100% efficiency because the low wake effects are not able to reduce the wind speeds below the rated speed.
- Vertical recovery is the main contributor to momentum replenishment in wind farms. Vertical transport of momentum by turbulent eddies into the turbine hub-height levels from above and below replenishes 70.8%–63.6% of the momentum loss in all but one cases. Momentum transport by horizontal advection plays a relatively weaker role replenishing only 6.6%–16.5% of the lost momentum. The relative contributions of horizontal and vertical recovery process are comparable only in the case with strong wind speeds and high inter-turbine spacing.
- The spatial patterns of vertical and horizontal recovery are complimentary. In general, vertical recovery is stronger in the interiors of the wind farms while horizontal recovery is stronger at the upwind edges. However, in sparsely spaced wind farms, horizontal recovery can also occur inside the wind farms as alternating bands normal to the direction of the flow.
- Vertical recovery increases with increasing wind farm density. It increases with increasing wind speed till the rated wind speed for the turbine after which, it starts to decrease. These systematic dependencies can be quantified using low-order empirical equations.
- Offshore wind farms do not demonstrate any synoptic scale effects on the atmosphere but can significantly alter mesoscale flow. Under strong wind conditions, a densely packed wind farm can generate a wake that is an order of magnitude longer

than the size of the wind farm. Mesoscale circulations created by the wind farms can transport momentum downward into the ABL from aloft. Thus, they aid in recovery by making more momentum available for replenishment.

- Horizontal TKE advection has minimal effects on recovery processes in wind farms. Deactivating horizontal TKE advection in WRF leads to small (up to 5%) changes in vertical recovery but horizontal recovery and spatial patterns of recovery processes are not affected.

There are scopes for improving upon this study. First, the MYNN closure scheme in WRF does not account for horizontal turbulent transport thereby limiting our ability to fully quantify horizontal replenishment. This is a difficult problem to resolve because it will require the development of an advanced closure scheme. Second, the wind turbine parameterization calculates the TKE generated by wind turbines as the difference between the momentum extracted by the turbine and the power generated by the turbine assuming that the electro-mechanical losses are negligible (Fitch et al., 2012). Archer et al. (2020) argues that electro-mechanical losses are not negligible. Comparing WRF and LES simulations, they contend that only about 25% of the difference between the momentum extraction and power generation goes to TKE while the rest is due to electro-mechanical losses. Hence, they suggested a correction factor of 0.25 for the coefficient that relates to turbulent kinetic energy (C_{TKE}). This issue needs in-depth investigation using observations to determine an appropriate partitioning between TKE generation and electro-mechanical losses. If the electro-mechanical losses are as large as 3 times the TKE generated as suggested by Archer et al. (2020), those losses must be accounted for by adding a source term in the temperature equation in the model to ensure energy conservation. Third, in this study we investigated the role of horizontal TKE advection in recovery processes. However, to fully understand the importance of horizontal TKE advection, we must explore its effects on power production and wakes. Fourth, due to the relatively coarse spatial resolution of the model, subgrid-scale wake interactions are not represented. Numerical experiments where the wake is explicitly parameterized (Volker et al., 2015) and wind farm layout effects are accounted for (Akbar and Porté-Agel, 2015) can improve our understanding of recovery processes.

This is a novel study that will make a significant contribution to the literature on wind energy meteorology. To the best of our knowledge, this is one of the first studies to look at wind farm replenishment processes under realistic conditions including the role of mesoscale processes. The empirical equations for vertical recovery developed in this study can perhaps be used to develop parameterizations for replenishment in analytical wake models. Overall, this study is likely to significantly advance our understanding of recovery processes in wind farms and wind farm-ABL interactions.

Code availability. The numerical experiments were conducted with WRF that is a well-known open-source software available in the public domain. Model configuration files and changes required in the source code to calculate the recoveries are available at <https://doi.org/10.5281/zenodo.4552414> (Gupta and Baidya Roy, 2021).

Data availability. The NCEP data used as initial and boundary conditions for the WRF model are available in the public domain.

Author contributions. SBR conceptualized the study. TG and SBR formulated the experiment design. TG conducted the numerical experiments and analyzed the results. TG and SBR wrote the manuscript.

Competing Interests. The authors declare that they have no conflict of interest.

Acknowledgement. The authors thank the IIT Delhi High-Performance Computing facility for providing computational resources.
