## Abstract.

Wind turbines are designed to minimize the cost of energy, a metric aimed at making wind competitive with other energy-producing technologies. However, now that wind energy is competitive, how can we increase its value for society? And how much would a societal gain cost other stakeholders, such as investors or consumers? This paper tries to answer these questions from the perspective of wind turbine design.

Although wind turbines produce green renewable energy, they also generate various impacts on the environment, as all human endeavours. Among all impacts, the present work adopts the environmental effects produced by a turbine over its entire life cycle, expressed in terms of CO<sub>2</sub>-equivalent emissions. A new approach to design is proposed, whereby Pareto fronts of solutions are computed to define optimal trade-offs between economic and environmental goals.

The new proposed methodology is demonstrated on the redesign of a baseline 3 MW wind turbine at two locations in Germany, differing for typical wind speeds. Among other results, it is found that, in these conditions, a 1% increase in the cost of energy can buy about a 5% decrease in the environmental impact of the turbine. Additionally, it is also observed that in the specific case of Germany, very low specific-power designs are typically favored, because they produce more energy at low wind speeds, where both the economic and environmental values of wind are higher.

Although limited to the sole optimization of wind-generating assets at two different locations, these results suggest the existence of new opportunities for the future development of wind energy where, by shifting the focus slightly away from a purely cost-driven short-term perspective, longer-term benefits for the environment (and, in turn, for society) may be obtained.

## 1 Introduction

The levelized cost of energy (LCOE) is defined as the net-present cost of an energy-producing technology over its lifetime per MWh supplied. LCOE is the metric that has been traditionally used to evaluate the competitiveness of energy sources. In recent years, the LCOE from wind (and from the sun) has experienced a dramatic decrease (Roser, 2021), which in turn has fueled an astonishing growth of wind energy and great expectations for its further expansion (Veers et al., 2019). About a decade ago, the International Energy Agency (IEA) Wind Task 26, which focuses on the cost of wind energy, identified a key driver for the future development of wind technology: the ability of generating cost parity – without direct policy support – with conventional sources, in a broad range of conditions and locations (Lantz et al., 2012). This indeed has largely happened and the evolution of wind energy technology continues at a fast pace, to the point that even offshore wind is rapidly marching

towards subsidy-free competitiveness (Jansen et al., 2020). The decrease in LCOE from wind has been partially driven by technological advancements, which have led to more reliable turbines characterized by higher hub heights and larger rotor diameters and, most importantly, much improved capacity factors. Additionally, economies of scale, increased competitiveness and an improved maturity of the sector have also contributed to the fall of LCOE witnessed in recent years (IRENA, 2021).

LCOE, however, paints only a partial view of a situation that is much more complex and articulated than what appears through cost alone (Joskow, 2011). A more holistic picture of the overall effects of renewable energies in general, and of wind in particular, can only be obtained when looking beyond cost metrics. Indeed, the urgency created by climate change, energy security and independence could not be clearer, as stressed by the headline news coming from all over the world every day.

In fact, the future participation of wind power in the energy market and, more broadly, its societal role will not only be shaped by its relative competitiveness, but also by its *value* (Beiter et al., 2021). The word *value* is generally understood in the literature as a synonym for *economic value*, which is a measure of the benefit provided to an actor by some good or service. In reality, in the case of an energy-generating technology, the concept of value is extremely broad. Leaving aside aspects such as energy security and independence, which are of crucial importance but also beyond the scope of the present analysis, it is worth noticing that the value of an energy technology cannot be quantified per se, because it depends on the interactions of that technology with the system in which it operates (Mai et al., 2021). For instance, the total system-value of an asset can be seen as the sum of different system-value components – including energy value, capacity value, ancillary service value and others (Mai et al., 2021). Additionally, due to supply and demand variability, the market price of electricity can vary widely, with high wholesale prices during peak demand times, which however can reach down to even negative values when large amounts of renewable energy are available in the grid. This fact, in addition to transmission and storage constraints, makes the economic value of electricity time- and location-specific (Hirth, 2012).

The importance of value has not gone unnoticed to the recent literature, and a range of options for increasing the economic value of wind energy have been explored. For instance, the geographic location of wind plants – and, more in general, of variable renewable energy plants – and the diversification of the energy mix are two strategies that can be used to this effect (Hirth and Mueller, 2016). Additionally, even the design characteristics of wind-generating assets (which is the focus of the present work) can change when considering value, rather than simply cost. In fact, some wind turbine design parameters – in particular hub height and specific power (i.e. rated power divided by rotor swept area) – can have a significant effect on economic value, as shown by Hirth and Mueller (2016); Lantz et al. (2017); Swisher et al. (2022), among others.

Economic cost and value, however, are actor-centric metrics, which mostly capture the investor point of view and, in turn, also the price eventually paid by the end consumer. Additionally, cost and value are short-term metrics: cost evolves rapidly from year to year, whereas value changes on even much faster time scales of minutes/hours. In this sense, economic cost and value – if used alone – seem to be rather myopic metrics for the design of a wind turbine. Indeed, time is ripe for looking beyond the benefit of the single actor and beyond short-term effects: wind energy should evolve to take into account also its broad and long-term impacts at the societal level. It is a major ambition of this paper to bring this new point of view to the design of wind turbines. Clearly, the same philosophy can also be applied to the design of wind plants and, more in general, to the design of the whole energy system.

From this broader perspective, the overarching goal of design becomes the alignment of short-term economic needs with long-term sustainable development goals. In fact, while it is necessary to enhance the economic value of wind energy to increase its competitiveness today, it is also our moral duty to improve the value of this technology for society now and into the future.

How can these broader goals be achieved? What are the new metrics that should be used to capture long-term societal effects? How can value be defined beyond its current economic meaning? How different would new more eco-conscious turbines be from standard LCOE-driven designs? And how much would a societal-level gain cost in terms of LCOE? These are some of the questions that are in need of answers, and that the present paper is trying to address, albeit in a preliminary and certainly yet somehow incomplete form.

There are undoubtedly several different options for including long-term societal effects in the design of wind turbines. This study focuses on the impact exerted by wind technology on the environment in terms of greenhouse gas (GHG) emissions. While GHG emissions clearly do not capture all effects of wind energy, they do provide for a major and quantifiable impact with long-term consequences. As long as they are quantifiable through some appropriate metric, other impacts could be included in a future even more general approach than the one presented here.

At first glance, it might seem unusual to speak about GHG emissions in the context of wind energy. After all, a wind turbine is an eco-friendly machine by definition, which captures kinetic energy from wind to produce electricity without directly releasing pollutants into the environment. Additionally, the deployment of each new wind turbine displaces a certain amount of GHG emissions, because the output of other more polluting energy sources can be correspondingly reduced. However, even wind turbines do have an environmental cost – as indeed all human activities –, and non-negligible amounts of GHGs are emitted throughout the different stages of their life. For example, the production of the large amount of steel needed for the tower, or the extraction of raw materials – such as the rare-earth elements present in the generator –, do have significant environmental impacts; additionally, the end-of-life (EOL) treatments of components with limited recyclability, such as blades largely made of reinforced thermoset polymers, do release polluting emissions into the atmosphere. More in general, all stages of the life-cycle of a turbine, from the extraction of raw materials all the way to the eventual disposal/recycling/repurposing of its components, generate impacts that can be quantified in terms of CO<sub>2</sub>-equivalent emissions. Given its importance, it is no surprise that the evaluation of the environmental cost of wind turbines is the subject of various recent studies, including Al-Behadili and El-Osta (2015); Ozoemena et al. (2018), among others. In addition to representing a meaningful metric per se, GHG emissions can also be turned into economic costs by using the societal cost of carbon (SCC), which is an estimate of the net present value of monetized social damages occurring from the emission of an additional metric ton of CO<sub>2</sub> (Gillingham and Stock, 2018; National Academies of Sciences, Engineering and Medicine, 2017). However, care should be exercised when using SCC, as it can take a large range of values, depending on the underlying assumptions and models (IPCC, 2007; Ricke et al., 2018; Kikstra et al., 2021).

While several publications propose metrics that capture the economic profitability of a wind turbine (Ueckerdt et al., 2013; Simpson et al., 2020; Mai et al., 2021), no metrics are yet available to describe the environmental cost and value of wind energy. To address this gap, this work introduces novel eco-conscious metrics that mirror existing economic ones. These metrics are

then used within a multi-objective design framework, which sizes some macroscopic parameters of a wind turbine (here rotor diameter and hub height) to find optimal trade-offs between economic and environmental perspectives.

100 The eco-conscious metrics are defined based on a life-cycle assessment (LCA) method, which has the added benefit of breaking down the contribution to the overall GHG emissions of a wind turbine by its components, materials and technological choices. This way, a ranking of the most harmful aspects of a design is readily obtained, revealing new opportunities and highlighting the most promising pathways for further mitigating GHG emissions beyond what is possible by sizing alone (Guilloré et al., 2022).

105 The paper is organized as follows. Section 2 defines metrics that quantitatively measure the cost and value of a wind-generating asset, both from the economic and the environmental perspectives. Next, Sect. 3 describes the methods that were used here to estimate the design metrics. In addition to standard energy production, mass, and cost models, this section describes and validates an LCA model whose goal is to estimate the CO<sub>2</sub>-equivalent emissions produced during each stage of the life and by each component of a wind turbine. The design approach is also formulated in this same section, in terms of single- and multi-objective constrained optimization problems. The new proposed methodology is exercised in Sect. 4, by redesigning  
110 a baseline 3 MW wind turbine at two different locations in Germany, one in the north and the other in the south of the country, characterized by different wind resources. The results are analyzed by looking at the trade-offs between economic and environmental metrics, and at the change in the design characteristics of the optimal turbines with respect to a standard LCOE-driven baseline. Finally, Sect. 5 summarizes the main findings of this study and offers an outlook towards future work.

## 2 Design metrics from economic and environmental perspectives

115 This section describes metrics for the preliminary design of an energy-generating unit using three common concepts: cost, value, and net value. In general, *cost* indicates the expense incurred for making a product or service, whereas *value* is a measure of the benefit brought by that good or service. The difference between cost and value is termed *net value*. In the present context, the good or service is the production of energy. The three terms cost, value and net value will be used with two different connotations: *economic*, when relating to money, and *environmental*, when relating to the GHGs emitted in the  
120 lifetime of an asset. These metrics are applicable to both single generating units (e.g., a wind turbine) or a plant (e.g., a wind farm), although the present work focuses only on the former case.

### 2.1 Economic perspective

The economic perspective results from an actor-centric point of view, e.g. the investor or the consumer, where the focus is primarily driven by short-term economic forces, such as revenue or out-of-pocket expenditure.

#### 125 2.1.1 Levelized Cost of Energy (LCOE)

LCOE is an estimate of the average net-present cost of each unit of energy produced over the lifetime of a generating asset. As such, this metric is widely used to assess the competitiveness of different energy technologies. LCOE is formally defined as the

ratio of the discounted lifetime costs with the discounted generated energy (Aldersey-Williams and Rubert, 2019; Duffy et al., 2020), i.e.

$$130 \quad \text{LCOE} \left[ \frac{\text{€}}{\text{MWh}} \right] = \frac{\text{Economic costs}}{\text{Energy production}} = \frac{\sum_{y=1}^Y \frac{C_y^{\text{CAPEX}} + C_y^{\text{OPEX}}}{(1+d)^y}}{\sum_{y=1}^Y \frac{E_y}{(1+d)^y}}, \quad (1)$$

where the subscript  $(\cdot)_y$  indicates the  $y$ -th year and  $Y$  is the lifetime in years, while  $C^{\text{CAPEX}}$  are the capital costs,  $C^{\text{OPEX}}$  are the operating and maintenance costs,  $E$  is the asset-generated energy, and finally  $d$  is the discount rate.

Capital costs include all expenditures incurred to manufacture the asset, while the operating and maintenance costs include all expenditures necessary for running the asset and maintaining it in working conditions (Joskow, 2011; Mai et al., 2021).

135 The discount rate is the interest rate used to determine the present value of future cash flows and, therefore, expresses the time value of money. The discount rate is often affected by significant uncertainties, which in turn may impact LCOE.

### 2.1.2 Levelized Value of Energy (LVOE)

LVOE is an estimate of the average net-present economic value of each unit of energy produced over the lifetime of a generating asset (Mai et al., 2021). Similarly to LCOE, LVOE is defined as

$$140 \quad \text{LVOE} \left[ \frac{\text{€}}{\text{MWh}} \right] = \frac{\text{Economic value}}{\text{Energy production}} = \frac{\sum_{y=1}^Y \frac{V_y}{(1+d)^y}}{\sum_{y=1}^Y \frac{E_y}{(1+d)^y}}. \quad (2)$$

The total revenue  $V_y$  generated by the asset in the  $y$ -th year is computed as a function of time  $t$  as

$$V_y = \int_{t=0}^{T_y} p(t)P(t) dt, \quad (3)$$

where  $T_y$  is the year duration,  $p(t)$  is the spot market price in €/MWh, and  $P(t)$  is the power produced by the unit at time instant  $t$ . Alternatively, the same quantity can be estimated as a function of wind speed  $U$  as

$$145 \quad V_y = T_y \int_{U_i}^{U_o} p_y(U)P(U)W_y(U) dU, \quad (4)$$

where  $U_i$  and  $U_o$  are respectively the cut-in and cut-out wind speeds,  $P(U)$  is the turbine power curve, while  $p_y(U)$  and  $W_y(U)$  are respectively the spot market price of energy and the Weibull probability density function at the site where the asset is installed in the year  $y$ .

### 2.1.3 Net Value of Energy (NVOE)

150 NVOE is defined as the difference between LVOE and LCOE (Mai et al., 2021), i.e.

$$\text{NVOE} \left[ \frac{\text{€}}{\text{MWh}} \right] = \frac{\text{Economic value} - \text{Economic cost}}{\text{Energy production}} = \text{LVOE} - \text{LCOE}. \quad (5)$$

## 2.2 Environmental perspective

The environmental perspective results from a societal point of view, in which the goal is no longer to achieve the cheapest energy in the short term, but rather the most sustainable one in the long term. The metrics presented here mirror the ones defined in the previous section. However, instead of considering the economic perspective, these novel metrics focus on the environmental impact and are quantified in terms of CO<sub>2</sub>-equivalent emissions.

As money is attributed a time value through the discount rate, even impacts could in principle be discounted, because emissions produced/displaced today might have a different effect from the ones of tomorrow. Indeed, time horizons are included in the estimation of the Global Warming Potential (GWP) that is used to convert the effects of different gases into equivalent CO<sub>2</sub> climate impacts (IPCC, 2007). However, discount rates for CO<sub>2</sub>-equivalent emissions are at present not available, and would probably be subjected to high uncertainties; therefore, discount rates were not considered in the definition of the environmental-based metrics.

### 2.2.1 Impact of Energy (IOE)

IOE represents an estimate of the average environmental cost of each unit of energy produced over the lifetime of a generating asset:

$$\text{IOE} \left[ \frac{\text{kg CO}_2\text{eq}}{\text{MWh}} \right] = \frac{\text{Environmental cost}}{\text{Energy production}} = \frac{\sum_{m=1}^M Q_m}{\sum_{y=1}^Y E_y}, \quad (6)$$

where  $Q_m$  is the CO<sub>2</sub>-equivalent GHG emissions during life stage  $m$ , and  $M$  is the total number of life stages of the asset, from the extraction of the raw materials all the way to EOL treatments. IOE is the environmental counterpart of LCOE, with the difference that decommissioning and EOL costs are generally not considered in the definition of the latter. Similar definitions of IOE have been given elsewhere using different names, as for example *Carbon Footprint* (Hauschild et al., 2018), *Emission Factor* (Koffi et al., 2017), *CO<sub>2</sub> Intensity* (Tremeac and Meunier, 2009), and *Global Warming Potential* (Ozoemena et al., 2018).

### 2.2.2 Environmental Value of Energy (EVOE)

EVOE is the counterpart of LVOE, and it is defined as the average environmental value per unit of energy generated by an asset over its lifetime:

$$\text{EVOE} \left[ \frac{\text{kg CO}_2\text{eq}}{\text{MWh}} \right] = \frac{\text{Environmental value}}{\text{Energy production}} = \frac{\sum_{y=1}^Y V_y^{\text{env}}}{\sum_{y=1}^Y E_y}. \quad (7)$$

The environmental value is quantified here in terms of the CO<sub>2</sub>-equivalent emissions that are displaced in the grid by the energy-producing asset. At time  $t$ , the energy mix is characterized by  $G_t$  generating technologies, each producing a certain power  $P_g(t)$ . The activation of a renewable generating unit that produces a power output  $P(t)$  displaces some output  $P_g^{\text{dis}}(t)$  of the  $g$ -th generating technology, such that  $P(t) = \sum_{g=1}^{G_t} P_g^{\text{dis}}(t)$ . Despite the activation of a renewable generating unit, the

time-dependent total power in the grid remains the same, as it is driven by demand. As a consequence, an environmental value  $V_y^{\text{env}}$  is generated over the time duration  $T_y$ , which is equal to the amount of displaced emissions, i.e.

$$V_y^{\text{env}} = \int_{t=0}^{T_y} \sum_{g=1}^{G_t} f_g(t) P_g^{\text{dis}}(t) dt. \quad (8)$$

The emission factor  $f_g$  quantifies the environmental impact of each generating technology in the mix. This quantity depends on time, because it is related to the operational conditions of the generating technology. For instance, operating a fossil-fueled plant at partial load has an efficiency penalty that increases the fuel consumption and the GHG emissions per unit of generated energy (Silver-Evans et al., 2012; Thomson et al., 2017). For simplicity, here each given technology  $g$  is associated with an average time-independent emission factor defined as

$$f_g = \frac{Q_g}{E_g}, \quad (9)$$

where  $Q_g$  indicates the average CO<sub>2</sub>-equivalent GHG emissions caused by the production of an amount of energy  $E_g$ .

The actual displacement of grid emissions is a complex time-dependent phenomenon (Hawkes, 2010; Thomson et al., 2017; Boeing et al., 2019). In fact, the only emissions that will be displaced are the ones of generators operating on the margin, i.e. the last generators needed to meet demand at a given time that are capable of rapidly adapting their power generation in response to a change in demand (Silver-Evans et al., 2012; Seckinger, 2021). Therefore, the actual displacement of grid emissions is determined by these marginal generators, which in turn depend on time-variable factors such as power demand, resource availability (e.g., wind speed and solar irradiation), or availability of other generation technologies. For simplicity, here it is assumed that all generating technologies are displaced equally, i.e.  $P_g^{\text{dis}}(t)/P_g(t) = P(t)/\sum_{g=1}^{G_t} P_g(t)$ , for each generating technology  $g$  at each time  $t$ . This is a conservative approach that is generally used to estimate emission displacements, and which has been shown to underestimate the real displacement potential of wind energy (Hawkes, 2010; Silver-Evans et al., 2012; Thomson et al., 2017). Under this hypothesis, the environmental value writes

$$V_y^{\text{env}} = \int_{t=0}^{T_y} \frac{\sum_{g=1}^{G_t} f_g P_g(t)}{\sum_{g=1}^{G_t} P_g(t)} P(t) dt = \int_{t=0}^{T_y} f_{\text{grid}}(t) P(t) dt. \quad (10)$$

The expression on the right hand side of the equation considers the whole grid as one aggregated generating unit, characterized by one equivalent time-dependent system-average emission factor  $f_{\text{grid}}(t)$ , which reflects the composition of the energy mix at each time instant (Thomson et al., 2017; Seckinger, 2021).

As for economic value  $V_y$ , also environmental value  $V_y^{\text{env}}$  can be estimated as a function of wind speed, instead of time, by the following expression

$$V_y^{\text{env}} = T_y \int_{U_i}^{U_o} f_{\text{grid}}(U) P(U) W_y(U) dU. \quad (11)$$

### 2.2.3 Net Environmental Value of Energy (NEVOE)

NEVOE is the counterpart of the economic metric NVOE, and it is defined as the difference between the environmental value  
210 of energy and the impact of energy, i.e.

$$\text{NEVOE} \left[ \frac{\text{kg CO}_2\text{eq}}{\text{MWh}} \right] = \frac{\text{Environmental value} - \text{Environmental cost}}{\text{Energy production}} = \text{EVOE} - \text{IOE}. \quad (12)$$

### 2.2.4 Future economic Societal Savings (FSS)

FSS estimates the future societal savings enabled by the displacement of GHG emissions, and writes

$$\text{FSS} \left[ \frac{\text{€}}{\text{MWh}} \right] = \text{SCC} \cdot \text{NEVOE}. \quad (13)$$

215 The societal cost of carbon (SCC) is the present discounted monetary value of the future damage caused to the environment by  
one metric ton increase in CO<sub>2</sub>-equivalent emissions (National Academies of Sciences, Engineering and Medicine, 2017). The  
quantification of SCC is clearly not a straightforward task. Indeed, the literature reports a large range of values (Ricke et al.,  
2018; Kikstra et al., 2021), mostly due to different assumptions on climate sensitivity, economic and non-economic impacts,  
and response lags, among others (IPCC, 2007). Additionally, NEVOE depends on EVOE that, as previously argued, is based  
220 on the simplifying assumption that all generation technologies are equally displaced by wind power; since this is hardly exactly  
true in practice, further uncertainties are introduced in the estimation of FSS.

## 3 Methods

This section describes the eco-conscious design of wind turbines, formulated as a constrained multi-objective optimization  
problem based on a number of interconnected underlying models. Figure 1 shows a schematic representation of the workflow  
225 and of its main components.

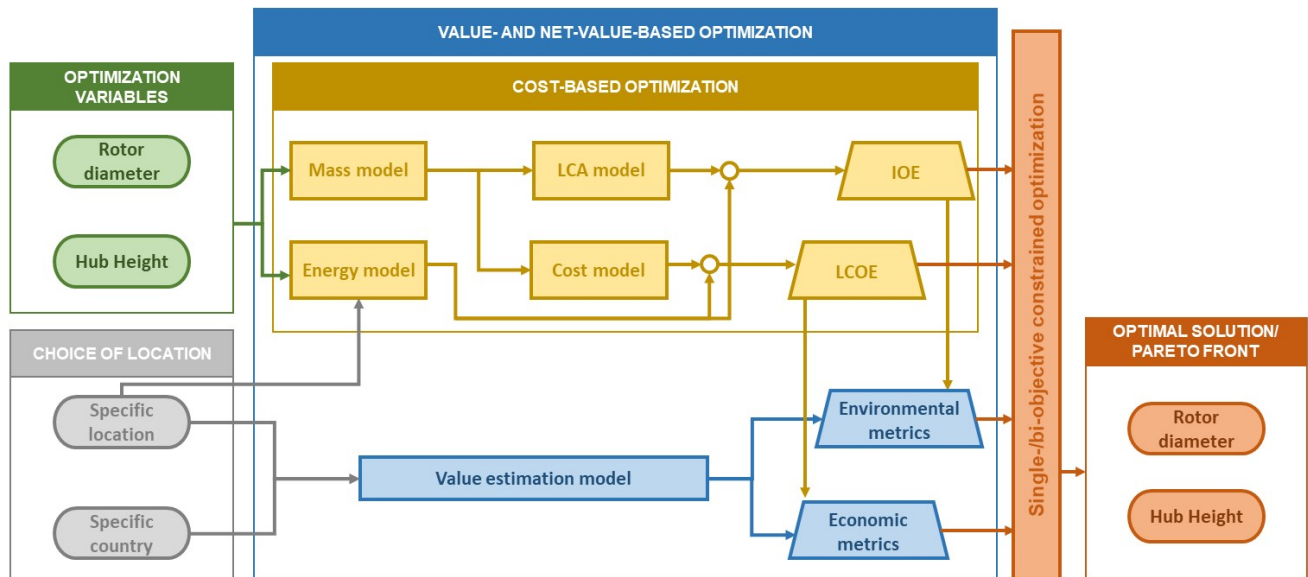

### 3.1 Energy model

The energy  $E_y$  produced by a wind turbine at a specific location in the year  $y$  is computed as

$$E_y = f_a f_p f_w T_y \int_{U_i}^{U_o} P(U) W_y(U) dU. \quad (14)$$

230 Three correction coefficients are included in the formula. The availability factor  $f_a$  accounts for failures, maintenance, and  
curtailment time, and it is set to the typical value of 0.98 (Vestas, 2011, 2013a, b; Pfaffel et al., 2017). The performance factor  
 $f_p$  considers different sources of losses due to turbulence, gusts, wakes, blade soiling/erosion, etc., and is set to the value of  
0.65, which is the lower limit of the range indicated in Lantz et al. (2017). The wind factor  $f_w$  accounts for possible deviations  
of the wind resource from the Weibull distribution, for example due to yearly variability (Lantz et al., 2017). Since the present  
analysis is based on actual historical data, which already includes any variability of the resource,  $f_w$  is set to the value of one.

**Figure 1.** Schematic illustration of the workflow for the eco-conscious multi-objective design optimization of wind turbines. Rounded squares represent variables, squares are models and trapezoids are merit functions.

### 235 3.2 Mass model

The mass estimation model is composed of three sub-models. The mass of the various turbine components is based on the 2017 NREL mass model (NREL, 2021), which is an updated version of the 2006 cost and scaling model (Fingersh et al., 2006). Based on the mass of the single components, a material breakdown model defines a bill of materials. This model is based on information sourced from several references (Rydh et al., 2004; Vestas, 2011, 2013a, b; Demir and Taskin, 2013; 240 Haapala and Prempreeda, 2014; Ozoemena et al., 2018), and includes 15 different material types: glass fiber, carbon fiber, epoxy resin, sandwich foam, alloyed steel, unalloyed steel, galvanized steel, copper, aluminium, PVC and other plastics, rubber, paint and coating, Neodymium permanent magnet (NdFeB), electronics, and concrete. Finally, a waste factor model estimates the quantity of material that is wasted during the different stages of the component lifetime. Waste factors for fiberglass, epoxy 245 the other materials.

The use of mass and scaling models is one of the various approximations of the present approach. More precise estimates of masses and bills of materials would clearly be possible by using detailed sizing procedures (Bortolotti et al., 2016; NREL, 2021). This level of complication and computational cost was however not deemed necessary for capturing general trends, which is the main goal here.

### 250 3.3 LCA model

LCA is a normed scientific methodology to exhaustively assess the environmental impacts of a product or a service, over its entire lifetime from cradle to grave. Here LCA is performed by an in-house-developed literature-sourced model that follows the environmental management standards of the International Organization for Standardization (ISO), according to ISO 14040 and ISO 14044 (Wolf et al., 2012; Hauschild et al., 2018).

255 The objective of the LCA model is to assess the complete life-cycle GHG emissions associated with the production of one functional unit, which in this case is 1 kWh of electricity. Emissions are broken down in terms of life-cycle stages, components and materials. Only climate-change-related environmental impacts are considered, and other effects such as human toxicity, eco-toxicity, acidification or resource depletion are excluded.

The model is formulated in a parametric way, i.e it is not specific to a given wind turbine model, and it is generally applicable  
260 to contemporary onshore variable-speed horizontal-axis technology. It is assumed that the turbine is installed in Europe between 2015 and 2025, and has a lifetime of 20 years. The machine is composed by rotor, nacelle, drivetrain, tower and foundations, and the elements within these components (e.g., the generator); connection to the grid, storage or other equipment and devices are outside of the scope of this model.

The processes involved in each one of the life-cycle stages are modeled based on typical scenarios from Rydh et al. (2004);  
265 Vestas (2011, 2013a, b); Demir and Taskin (2013); Haapala and Prempreeda (2014); Ozoemena et al. (2018), among others. Emission factors are based on Ecoinvent IPCC 2013 (Myhre et al., 2013; Ecoinvent, 2019; Bourgault, 2019).

This LCA method considers the atmospheric emissions of all gases that are recognized to have a greenhouse effect, including CO<sub>2</sub>, CH<sub>4</sub>, N<sub>2</sub>O and fluorinated gases. For each one of these gases, the mass of CO<sub>2</sub> that would have the same greenhouse effect is defined and used as a measure of impact (Myhre et al., 2013; Bourgault, 2019).

#### 270 3.3.1 Life-cycle stages

This section briefly defines the life-stages considered in the present work, and the assumptions taken in each of them. For further details, the reader is referred to Guilloré et al. (2022).

– Life-cycle stage 1: Raw material extraction and processing. This stage accounts for the environmental impact upstream of the purchasing of a unit of ready-to-use material for manufacturing. Raw material extraction and processing emissions  
275 are modelled according to Ecoinvent (2019).

– Life-cycle stage 2: Transportation of raw materials to manufacturing sites. This stage considers both direct emissions caused by the burning of transportation fuel, and indirect emissions produced in the life-cycle of the fuel from well to tank. Indirect emissions from the production of the transportation technology itself are also included. Based on Vestas (2011, 2013a, b), it is assumed that all materials are transported over a distance of 600 km to the manufacturing site,  
280 except for concrete, which is only transported over a distance of 50 km. Emission factors for transportation are considered

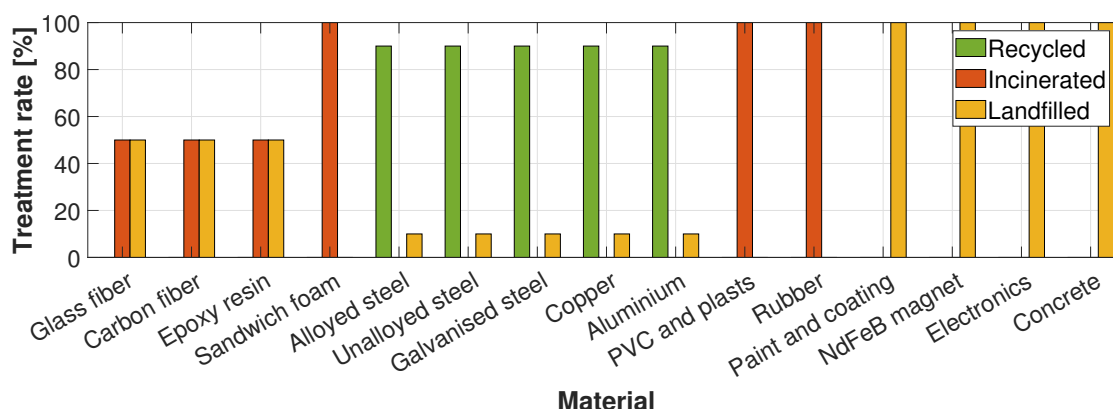

from Ecoinvent (2019), assuming that materials are transported by freights and lorries heavier than 32 t, with EURO4 exhaust emissions (Spielmann et al., 2007).

- Life-cycle stage 3: Wind turbine component manufacturing. This stage considers the environmental impact of the energy consumed for the transformation of the materials into wind turbine components. The upstream environmental impact of the energy consumed – which is generally electricity from the grid, whose impact depends on the specific electricity mix – is also considered. Manufacturing emissions are obtained from several sources (Song et al., 2009; Hill and Norton, 2018; Ecoinvent, 2019).
- Life-cycle stage 4: Transportation of the components to the wind plant site. For this stage, the same assumptions on transportation vehicles of the life-cycle stage 2 are taken, adding ship transport. Assumptions on transportation distances are modeled according to Vestas (2011, 2013a, b).
- Life-cycle stage 5: Assembly and installation of the wind turbine. This life-cycle stage considers the direct and indirect emissions from the assembly and installation of the different wind turbine components. It is assumed that a hydraulic crane is required for 16 hours of work (Rydh et al., 2004; Ozoemena et al., 2018).
- Life-cycle stage 6: Operation and maintenance (O&M). This stage considers different impacts related to operation and maintenance, and is defined according to Rydh et al. (2004); Vestas (2011, 2013a, b); Demir and Taskin (2013); Haapala and Prempreeda (2014); Ozoemena et al. (2018). The GHG emitted during O&M are determined as the sum of the emissions related to the turbine lubricant oil change, to the use of an inspection van and maintenance crane, and related to the replacement of components, as detailed next.
  - Lubricant Oil. The oil employed for the regular change of gearbox oil and lubricant is considered. Assumptions are taken according to Rydh et al. (2004), Haapala and Prempreeda (2014) and Ozoemena et al. (2018).
  - Inspection van. It is assumed that a roundtrip from the maintenance base is required every 6 months (Ozoemena et al., 2018) with a diesel passenger car of emission category EURO4 (Spielmann et al., 2007).
  - Maintenance Crane. It is considered that heavy crane machinery is required for a total of 8 hours over the turbine lifetime (Ozoemena et al., 2018).
  - Replacements of components. All components may be subjected to failures, and generally several parts need to be replaced over the lifetime of a wind turbine. Failure rates are modeled according to Tremeac and Meunier (2009); Demir and Taskin (2013); Haapala and Prempreeda (2014); Ozoemena et al. (2018). Life-cycle stages 1 to 5 are used to estimate the emissions resulting from the spare components that need to be replaced. Additionally, the impact of the transport of the replacement components to the site is doubled, to account for the trip back with the defect replaced components.

– Life-cycle stage 7: Decommission and transportation of parts. This life-cycle stage considers 16 hours of crane work, as described in Rydh et al. (2004) and Ozoemena et al. (2018). The same assumptions taken for life-cycle stage 4 are used also here to estimate the emissions caused by the transportation of the parts to their EOL treatment centers.

– Life-cycle stage 8: EOL treatment. The EOL scenario is a key stage in the life-cycle of a wind turbine. Three treatments are considered in this work: recycling, incineration, and landfilling. In accordance with ISO 14044 (Wolf et al., 2012; Hauschild et al., 2018), the approach of closed-loop material cycle is considered, where full credit is given to the emissions of life-cycle stage 1 linked to the recycled materials. Recycled materials are therefore considered to have a negative impact, and thus represent environmental benefits. Metals – steel, copper, and aluminium – have high recyclability rates, as shown in Fig. 2 (Tremeac and Meunier, 2009; Vestas, 2011, 2013a, b; Haapala and Prempreeda, 2014; Schmid, 2020). On the other hand, there is no mature technology yet for the recycling of thermoset glass-fiber reinforced polymers (GFRP), which are currently incinerated or landfilled (Schmid, 2020; Beauson et al., 2022), depending on the legislation of the country. A representative scenario of 50% incineration and 50% landfilling is assumed here, as described in Vestas (2011, 2013a, b). The overall EOL impact is the sum of the recycling, incineration and landfilling environmental impacts. This quantity can either be positive or negative, depending on whether or not the recycling benefits outweigh the incineration and landfilling environmental impacts.

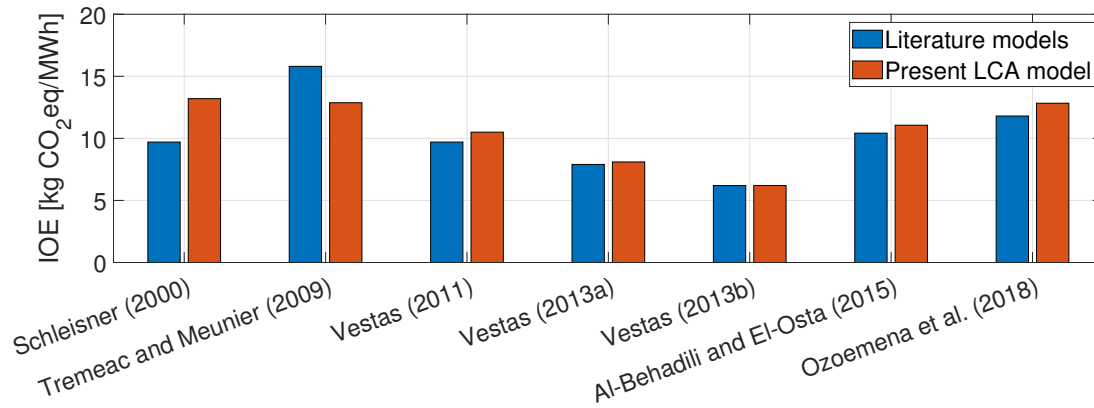

**Figure 2.** EOL treatment rates (by mass) for various materials types.

### 3.3.2 Validation of the LCA model

The LCA model was validated against results published by Schleisner (2000); Tremeac and Meunier (2009); Vestas (2011, 2013a, b); Al-Behadili and El-Osta (2015); Ozoemena et al. (2018), as shown in Fig. 3.

In general, there is a good match between previous studies and the present model. Differences arise due to non identical hypotheses and assumptions, for instance in life-cycle scenarios, bill of materials, or energy production. Indeed, several pub-

**Figure 3.** Comparison of the environmental impact obtained with the present LCA model and with results sourced from the literature.

lications do not thoroughly detail the assumptions taken, or the processes considered in the different life-stage cycles, which hinders an exact comparison.

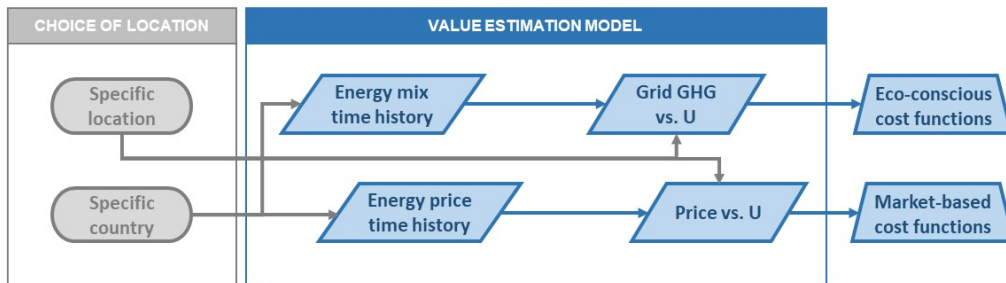

### 3.4 Cost model

Costs are based on the 2015 NREL cost model (NREL, 2021), converted to 2017€ values. The model estimates the initial  
335 capital costs and O&M costs. Initial capital costs include rotor, nacelle, drivetrain, tower and foundations, as well as balance  
of station (BOS) costs, including transportation, assembly and installation. Additional BOS-related costs such as engineering,  
permitting, and grid connection are excluded, as their environmental impact is not considered in the present LCA model.  
Annual operating expenses include O&M costs, whereas land lease costs are not considered.

### 3.5 Value estimation model

340 This model estimates the economic and environmental value of a wind turbine, for a specific location and a specific time frame,  
as illustrated in Fig. 4.

The estimation of economic value is based on historical data, using Eq. (4). Time series of spot market price were correlated  
with time series of wind speed at a specific location and hub height, resulting in the price-wind model  $p_y(U)$ . Similarly, the  
environmental value was estimated with Eq. (11), where the grid average emission factor  $f_{\text{grid}}(U)$  was computed based on the  
345 energy mix time history of the country, or region, where the turbine is located. The average emission factor of each generation  
technology in the mix was obtained from Ecoinvent (2019), and only considers operational emissions (Thomson et al., 2017;  
Boeing et al., 2019). Wind speed time histories were adjusted to the turbine hub height based on the site mean shear, and used  
to estimate the Weibull distribution, spot market price, and grid-average emission factor.

**Figure 4.** Workflow of the value estimation model of Fig. 1. Rounded squares represent variables, squares are models, rhombuses are data, and trapezoids are merit functions.

### 3.6 Optimal design problems

350 In this work two different design problems are considered, based on either a single- or a two- objective constrained optimization. In both cases, the problem is formulated as:

$$\min_{\mathbf{p}} J(\mathbf{p}), \quad (15a)$$

$$\text{such that: } \mathbf{c}(\mathbf{p}) \leq 0, \quad (15b)$$

355 where  $J$  is the cost function, chosen among the design metrics of Sect. 2,  $\mathbf{p} = (D, H)$  are the design variables, with  $D$  the rotor diameter and  $H$  the hub height. Finally,  $\mathbf{c}$  are inequality constraints that enforce desired design conditions.

The single-objective optimization problem is solved with a sequential quadratic programming algorithm, in which gradients are computed by means of finite differences (Mathworks, 2019). The multi-objective optimization problem is solved with a non-dominating sorting genetic algorithm (NSGA-II) (Seshadri, 2020).

360 This simplified design problem is termed *preliminary*, in the sense that it only determines macroscopic parameters of the machine. Based on the results of this preliminary sizing, standard detailed design procedures should be used to dimension all components and systems.

## 4 Case study: cost-driven and eco-conscious designs of a wind turbine for Germany

365 Trade-offs were investigated between an economic and an environmental point of view, by analyzing the characteristics of the resulting optimal turbines with respect to a standard LCOE-driven baseline assumed as reference. The study was performed with the methods described in the previous sections, where the cost model was tuned to represent the situation in Germany according to Deutsche WindGuard (2018) and Duffy et al. (2020).

#### 4.1 Baseline description

The baseline is chosen to represent a recent LCOE-driven industrial product, and corresponds to a wind class IIA machine with a rated power of 3 MW, a rotor diameter of 115.7 m, a hub height of 92 m, and a lifetime of 20 years. These characteristics make the baseline loosely resemble one of the several E-115/3.0 MW models (Enercon, 2021) that, according to Deutsche WindGuard (2018), was the most installed turbine in Germany in 2016, 2017 and 2018 – the years considered in this study. This wind turbine has an IOE of 11.83 kg CO<sub>2</sub>eq/MWh and an LCOE of 35.6 €/MWh, according to the models of §3.4. Given the typical large uncertainties in the discount rate,  $d = 0$  was assumed in Eq. (1).

Figure 5 shows a breakdown of the environmental cost of the wind turbine by its principal components. The figure reports both absolute emissions per unit of component mass (green bars), as well as relative emissions with respect to the overall impact produced by the wind turbine (blue bars). Tower and foundations play the largest role in the overall IOE, each one accounting for about 20% of the total. The high environmental impact of the foundations is due to the significant amount of concrete that they require, and the negative effects caused by landfilling at the end of life. The tower, on the other hand, is made of steel, a material with a high recyclability rate (see Fig. 2). Notwithstanding the resulting emissions credits at the end of life, the tower still has a significant environmental impact because of its very large mass. Blades also present a large environmental impact, because of their reduced recyclability. Electronics have the highest impact per unit of material, but a small overall contribution due to their reduced mass.

**Figure 5.** Environmental impact of the life-cycle of each component of the baseline wind turbine, expressed in terms of absolute emissions per unit of component mass (green bars), and relative percent emissions with respect to the overall impact of the machine (blue bars).

## 4.2 Cost-driven design

The baseline turbine was then optimized from an economic-environmental cost perspective. Only hub height and rotor diameter are free design variables, whereas rated power is held fixed to the baseline value. The bi-objective design problem is expressed by Eq. (15), where  $J$  considers economic cost by LCOE and environmental cost by IOE. The design constraints of Eq. (15b) are set to express conditions on height/diameter ratio and on the specific power of the turbine:

$$0.5 < \frac{H}{D} < 1, \quad (16a)$$

$$100 \text{ MWm}^{-2} < \frac{P_r}{A} < 350 \text{ MWm}^{-2}, \quad (16b)$$

where  $P_r$  is the rated power, and  $A = \pi D^2/4$  is the rotor swept area. These same inequality constraints were used also in all the following design problems.

Figure 6a shows the resulting Pareto front of optimal non-dominating solutions. The corresponding optimal rotor diameters and hub heights of the Pareto front designs are shown in Fig. 6b.

**Figure 6.** Pareto front of IOE vs. LCOE (a). Rotor diameter and hub height of the Pareto optimal designs (b). Differences are expressed with respect to the baseline configuration, whose dimensions are given by black  $\blacktriangle$  (diameter) and  $\blackstar$  (hub height) symbols.

Results indicate that a decrease in IOE can be achieved by reducing the overall size of the turbine, both in terms of rotor diameter and hub height; since rated power is held fixed, the resulting turbines have an increased specific power  $P_r/A$ . A maximum reduction in IOE of about 8% is achieved at the expense of an increase of about 5% in LCOE.

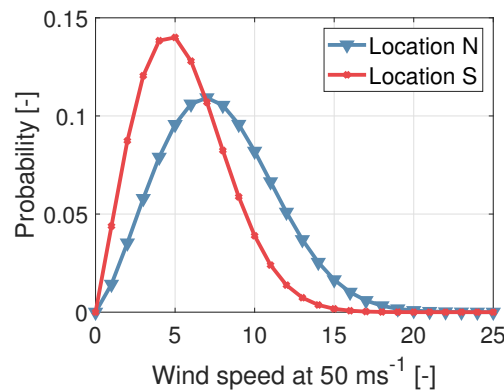

However, what is more interesting to observe is that the curve is very steep close to the point of minimum LCOE. This means that a significant reduction in IOE can be achieved with marginal increments in LCOE. For instance, a turbine with a 110 m diameter and a 75 m hub height presents an LCOE that is only 1% higher than the baseline, while at the same time achieving an IOE reduction of about 5%. This result is achieved by the design of smaller rotors and shorter towers that, although imply a somewhat reduced power capture, have lower environmental costs.

### 4.3 Value-driven design

The previous section showed that, from a cost perspective, there is room to reduce the impact on the environment if one is willing to accept some increase in the cost of energy from wind. However, cost by itself does not capture the full complexity of the problem, and further insight can be obtained by including also value in the analysis.

To this end, the turbine was optimized considering economic and environmental value, instead of cost. Two different locations in Germany were selected: one in the north of the country (labelled LN in the following), characterized by very good wind conditions, and a second one in the south (labelled LS), with lower average wind speeds. The site wind characteristics are more precisely shown by the two Weibull distributions reported in Fig. 7 (NEWA, 2021).

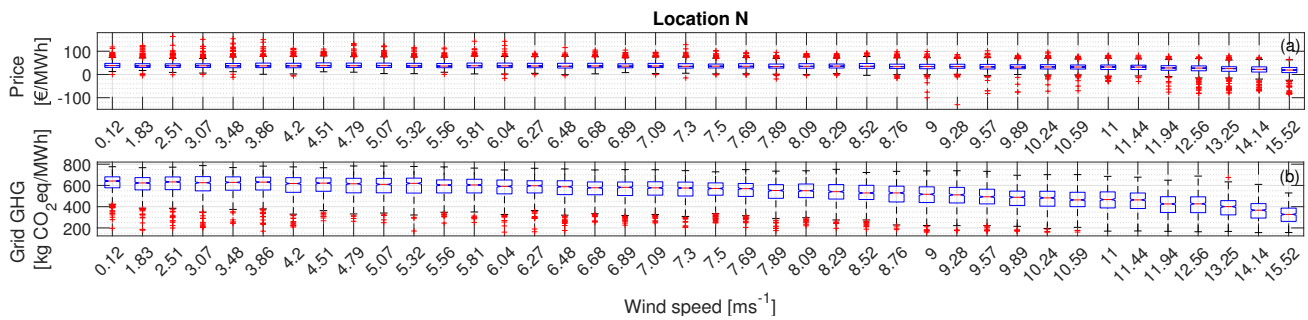

**Figure 7.** Weibull distributions at the northern and southern German locations, at 50 m height above ground.

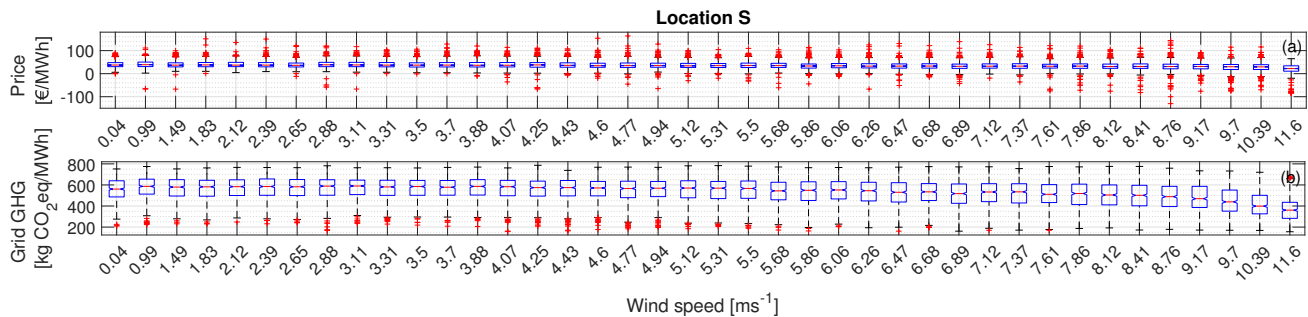

The economic and environmental values were estimated with the model described in §3.5. Day-ahead spot market price and energy mix time series were collected from the SMARD database (SMARD, 2020), and completed with wind speed time series obtained from NEWA (2021), considering the years 2016, 2017 and 2018. All quantities were sorted into 50 wind speed bins, each containing the same number of data points. The resulting interpolating curves were extrapolated above the last bin upper boundary all the way to cut-out wind speed.

Figure 8 and 9 respectively show the histograms of spot market price and grid GHG emissions vs. wind speed at 50 m height at the LN and LS sites, for the three considered years. For both locations, the spot market price and grid GHG emissions exhibit a decreasing trend with respect to wind speed. In fact, at low wind speeds there is a large amount of energy from coal-fired power stations in the energy mix, pushing both the price and grid GHG emissions up. With higher wind speeds, the amount of

wind energy in the grid increases, so that more expensive and polluting energy sources are displaced. This is clearly a partial  
 420 view of the behavior of a very complex system, which does not only depend on wind speed.

**Figure 8.** Spot market price (a) and grid GHG emissions (b) vs. wind speed at 50 m for LN (site in the north of Germany).

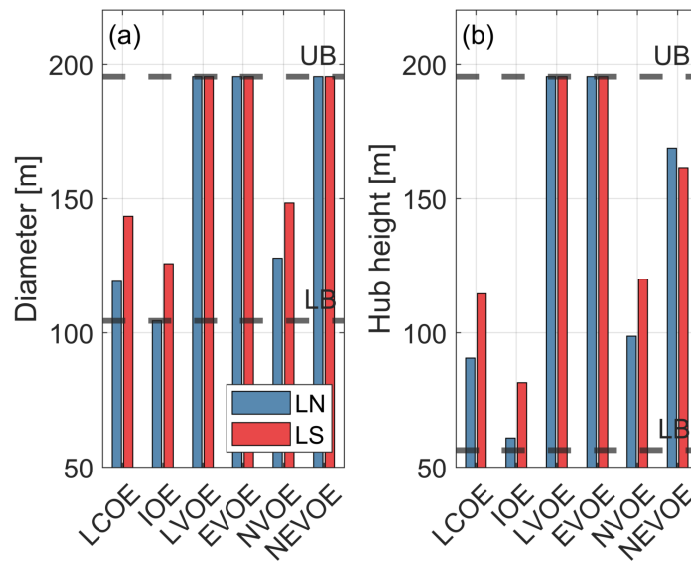

**Figure 9.** Spot market price (a) and grid GHG emissions (b) vs. wind speed at 50 m for LS (site in the south of Germany).

### 4.3.1 Single-objective optimization

First, a single-objective optimization was run for each metric at the two locations in order to analyze the behavior of the optimal turbine design characteristics. The resulting diameters are shown in Fig. 10a, while the hub heights are given in Fig. 10b. The figures of merit are organized from left to right as follows: the first two are cost-based metrics (LCOE and IOE), the next two are value-based metrics (LVOE and EVOE), and finally the last two are net-value-based metrics that consider both cost and value (NVOE and NEVOE).  
 425

Analyzing first the cost-based perspective, results indicate that, as already observed in §4.2, a turbine designed for minimum IOE has a smaller rotor and a shorter tower than a turbine designed for minimum LCOE, on account of their large environmental impact. For both metrics, the southern location LS requires a turbine with a larger rotor and a taller tower than the northern  
 430 location, due to lower typical wind speeds.

From a value point of view, no differences in rotor diameter and hub height are found between the economic (LVOE) and the environmental (EVOE) perspectives. In fact, for both metrics, the optimal rotor and hub height are as large as possible, hitting the lower bound for specific power. This can be explained by noticing that, since low wind speeds are associated with larger

**Figure 10.** Optimal diameters (a) and hub heights (b) for each single objective function, for the two locations. Cost-based metrics: LCOE, IOE; value-based metrics: LVOE, EVOE; net-value-based metrics: NVOE, NEVOE.

economic and environmental values (see Figs. 8 and 9), optimal economic/environmental value-driven designs tend to produce  
 435 as much as possible at low wind speeds. This can be achieved by minimizing the extent of the partial load region (region II),  
 which is obtained by reducing the rated wind speed  $V_r = \sqrt[3]{2P_r/\rho AC_{P_{\max}}}$ , where  $\rho$  is the air density and  $C_{P_{\max}}$  the maximum  
 power coefficient of the rotor. As shown by the formula, since  $C_{P_{\max}}$  is limited by physics, for given ambient conditions  $\rho$ ,  $V_r$   
 decreases for smaller specific powers  $P_r/A$ . These results are in line with similar studies that have shown how low specific  
 power turbines have a higher economic value (Hirth and Mueller, 2016; Swisher et al., 2022).

440 Finally, both NVOE and NEVOE – which consider both cost and value – lead to configurations that can be interpreted  
 as compromises between the cost and value perspective. For NVOE, as economic value has the same order of magnitude as  
 economic cost, the solution presents a rotor diameter and hub height that fall in between the cost- and value-based solutions.  
 On the other hand, for NEVOE the environmental value is one order of magnitude larger than the environmental cost, and this  
 drives the rotor size, which even in this case hits the lower limit for specific power. The introduction of cost, however, penalizes  
 445 the hub height, which is reduced with respect to the value-based solution because of the large influence of the tower.

### 4.3.2 Bi-objective optimization

Next, trade-offs between the economic and environmental net value were analyzed through a Pareto front, computed solving  
 the bi-objective optimization problem expressed by Eq. (15). The LCOE-driven designs obtained in the previous section and  
 displayed in Fig. 10 are used here as baselines for each location.

450 For the two sites LN and LS, Fig. 11a shows the Pareto front NEVOE vs. NVOE, while Fig. 11b reports the change in rotor diameter and hub height with respect to the baselines, as functions of NVOE. As already observed in Fig. 6, even in this case results indicate that it is possible to increase the environmental net value (NEVOE) without significantly decreasing the economic net value (NVOE). For example, accepting a decrease in NVOE of 1 €/MWh buys half of all possible improvement in NEVOE, for both locations. This is achieved with larger diameters (i.e., smaller specific powers), and taller hub heights.

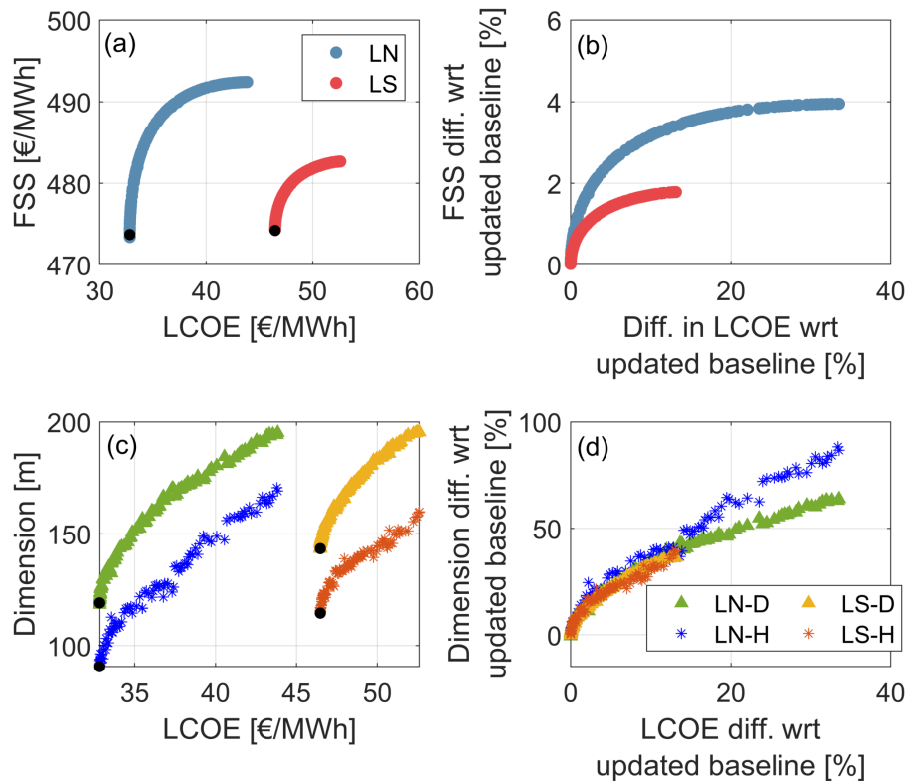

455 Another interesting observation is that both locations present the same Pareto front shape. While LN has a better economical performance than LS (as expected, because of the better wind resource), both locations appear to have a similar net value from an environmental point of view.

**Figure 11.** Pareto front between a net environmental value point of view (NEVOE) and a net economic value point of view (NVOE) (a). Optimal diameters and hub heights for the solutions of the Pareto front, expressed as percent changes with respect to the corresponding LCOE-driven baseline of each location (b)

Finally, environmental net value was used to estimate future economic societal savings, multiplying NEVOE by SCC, as described in §2.2.4. An SCC of 1 €/kg CO<sub>2</sub>eq was considered in this work. However, as previously noted, SCC can take widely different values depending on the assumptions and models considered (IPCC, 2007). Although this makes the resulting FSS values affected by high uncertainty, the analysis is still useful because it may reveal interesting trends.

Figure 12 presents the designs that result from trading LCOE – the metric currently used to assess the competitiveness of an energy-producing technology – with FSS – the metric proposed here to estimate the future societal savings obtained by deploying an energy-producing technology.

**Figure 12.** Pareto front between FSS and LCOE, in absolute values (a), and relative to the LCOE-driven baseline of each location (b). Optimal diameters and hub heights of the Pareto solutions in absolute values (c), and relative to the corresponding LCOE-driven baseline of each location(d).

465 The Pareto front is displayed in absolute quantities in Fig. 12a, and relative to the LCOE-driven baselines in Fig. 12b. Similarly, the solutions of the Pareto front are displayed in absolute quantities in Fig. 12c, and relative to the baseline configurations in Fig. 12d. The values shown here should be treated only as rough estimates because of the many simplifications and assumptions. Nonetheless, some interesting trends seem to emerge.

First, as expected, the current LCOE-driven designs (which capture the individual point of the view of the investor and  
 470 consumer) are not optimal from the societal point of view. This means that, to improve the societal metric, an individual would have to accept an increase in out-of-pocket expenditure.

Second, the largest opportunities appear to be close to the LCOE optima, where the curves are very steep. This means that even marginal increases in cost can have an impact on the societal savings. However, away from the LCOE optima, the curves level off, meaning that optimal societal savings would require significant increases in cost, which would probably not  
 475 be acceptable by consumers.

Third, the general trend of the Pareto solutions is similar at both sites. Hence, even at sites characterized by poor wind resources, there is room for improving the societal value of wind energy.

480 Fourth, although better wind resources at the northern Germany site are associated with lower costs, the societal savings are similar at both locations. This is an interesting finding, because it implies that the installation of each new wind turbine is of a similar environmental and societal value, independently of the characteristics of the site. However, since sites with worse wind resources are penalized by a higher LCOE, policies may be needed that – by taking a long-term view on future economic societal savings – increase in the short-term the competitiveness of wind turbines at these locations.

## 5 Conclusions

This paper has explored the idea of enhancing the inherent societal value of wind turbines by changing the way they are  
485 designed. While societal value is clearly a very broad concept, the focus here is on the societal benefits brought by the displacement of environmental emissions made possible by the generation of renewable energy from wind.

The paper first defined metrics that quantify the societal value of wind turbines based on two concepts: *environmental cost* and *environmental value*. The former expresses the GHG emissions generated throughout the entire lifetime of a wind turbine, while the latter quantifies the displacement of GHG emissions from the grid caused by the deployment of a wind turbine; in  
490 both cases, these quantities are computed per unit of generated energy. These metrics are defined mirroring already existing economic metrics, based on the familiar concepts of economic cost and value.

Next, a toolchain was described, which implements a complete LCA model capable of estimating the emissions of a wind turbine throughout its lifetime, broken down in life-cycle stages, components and materials. Using the LCA model, together with energy and mass models, a simplified design problem was formulated, which can determine the optimal geometric characteristics of a wind turbine (in terms of its rotor diameter and hub height) for a given rated power. The resulting preliminary  
495 design gives only the overall dimensions of the turbine, and would have to be followed by a detailed design of its aerodynamics, structures, systems and control laws. The design problem can be formulated either as a single or a multi(bi)-objective minimization. The classical standard approach of designing wind turbines by minimizing LCOE is included in the formulation as a special case.

500 A 3 MW wind turbine, representative of the LCOE-driven machines currently installed in Germany, was chosen as a baseline reference to study the effects of considering various possible economic and/or environmental metrics in the preliminary sizing problem.

The environmental assessment of the baseline highlighted the large contribution of the foundations – made of concrete –, and of the tower – made of highly-recyclable steel – to the total life-cycle emissions of the wind turbine. These components  
505 have low emission factors – i.e., a low environmental cost per unit of mass – but require large quantities of material. Electronic components, on the other hand, have a modest overall contribution even if they have very high emission factors. Clearly, the overall environmental cost of a wind turbine depends on the technological solutions chosen for its main components. Indeed, choices at all stages of the life-cycle – from the processes used to mine or produce the materials to EOL decisions –

510 have implications on both the economic and environmental costs, as the two aspects are intimately connected. Understanding the environmental cost of each material, each component and each life-cycle stage is critical for identifying alternatives that minimize both forms of cost.

The baseline turbine was then redesigned using a bi-objective optimization for LCOE and IOE, obtaining a Pareto front of optimal non-dominating solutions. This family of solutions can be interpreted as the cost-optimal designs that trade the point of view of the individual (LCOE) with the point of view of society (IOE). It is one of the main findings of this work that the Pareto front is very steep around the LCOE-optimal designs. For the case considered here, it appears that an LCOE increase of only 1% can buy an IOE decreases of 5%. In other words, it pays off to be altruistic, and a large societal impact can be achieved if consumers are willing to pay a bit more for the energy that they consume.

520 Finally, the effects of value and net value were considered, again looking at both the economic and environmental points of view. Value-based metrics are location- and time-dependent quantities, and therefore tightly linked to the site where the wind turbine is installed. Two locations were considered: one in the north of Germany with better wind resources, and one in the south of the country, where typical wind speeds are lower. Results show that, for the years considered here, spot market price and grid GHG emissions are generally higher at low wind speeds for both sites, as generally expected.

525 A Pareto front of optimal solutions was generated that trades-off economic net value – i.e. the difference between economic value and cost –, and environmental net value – similarly defined, but considering emissions. Results indicate that, here again, the curves are very steep close to the net-value economic optima. Therefore, even from this point of view altruism pays off, and significant net value environmental gains can be achieved with rather small losses in net economic value.

530 Unsurprisingly, economic net values were found to be profoundly different at the two locations, the better wind resources in the north being associated with much lower values of NVOE. However, interestingly, the environmental net values at the two locations were found to be very similar. This result points to the fact that wind turbines have similar beneficial effects no matter where they are installed, with little sensitivity to the local wind resources. Therefore, wind energy is a sensible choice also for places with modest wind conditions, as for example the south of Germany. Clearly, these results should be further explored considering transmission constraints.

535 Additionally, it was found that environmental value is one order of magnitude larger than environmental cost, whereas economic value and cost are of the same order of magnitude. Consequently, the economic net value is more sensitive than the environmental one to the characteristics of the location.

Finally, future societal savings were estimated by using the societal cost of carbon, which quantifies the present cost of future damage caused by the emission of one additional unit of CO<sub>2</sub>eq. Similar conclusions as the ones discussed earlier can be drawn from these results.

540 This study shows that, in general, low specific power turbines present higher economic and environmental values, at the expense of a higher cost of energy. This is due to the fact that, with the present technology, the larger energy captured by a bigger rotor does not generally compensate its larger cost. However, the present findings highlight that the benefits of low specific power turbines go well beyond what is quantified through LCOE alone, which, in hindsight, appears to be a rather myopic and incomplete metric. Indeed, several studies have shown that low specific power turbines bring benefits beyond

545 economic value: for instance they can better utilize the transmission system, reduce forecasting errors, and could lead to cheaper financing (Hirth and Mueller, 2016; Swisher et al., 2022).

The present work and its findings are affected by several limitations.

First, the LCA, mass, and cost models are based on general trends of current wind turbines. Clearly, low specific power machines push the boundaries of these models. More accurate estimates could be obtained by using detailed design procedures that, from the rough sizing produced by the present approach, yield refined designs.

550 Additionally, the trends shown here are only valid for Germany in the years considered. Clearly, both economic and environmental value depend on the time-specific composition of the energy mix, whose behavior is very complex and depends on more variables than just wind speed, as it was assumed here for simplicity. The assumptions taken in this work are clearly oversimplifications that try to produce initial rough preliminary trends. Future work should couple the present models with more sophisticated descriptions of the energy mix, able to capture their present and future composition. In fact, understanding  
555 how the economic and environmental value of wind energy will develop in the next years is yet another crucial element that deserves further work. Indeed, as wind penetration is set to increase, the economic value of wind energy is expected to decrease, an effect called “self-cannibalization”. However, predicting the impact of an increase in wind energy is not straightforward, as the final effects depend on the emission factors of the generating technologies in the energy mix. The impact on displaced GHG is even more complex to estimate, as it depends on the emission factors of the generating technologies operating on the  
560 margin, which are not only strongly country-specific, but also time-dependent. Here again, these effects can only be properly captured by using more sophisticated models, including an electricity market model.

Notwithstanding these limitations, it was one major ambition of this paper to bring the inherent societal value of wind turbines under the spotlight. While this study only focused on the changes in overall dimensions (and, in turn, specific power) of the machine, the potential for further improvements is much larger than what would appear by this simple analysis alone. In  
565 fact, the same metrics developed here can also be employed to guide the choice of technologies and the detailed design of the various components of a wind turbine. In addition, beyond the single wind turbine case analyzed here, this new eco-conscious design philosophy can be used to design a whole wind plant.

*Author contributions.* HC led the development of the work, in close collaboration with AG and CLB. AG developed and validated the LCA model. CLB supervised the research. HC and CLB wrote the paper, with inputs from AG. All authors provided important input to this  
570 research work through discussions, feedback and by writing the paper.

	<i>t</i>	Time
	CO <sub>2</sub> eq	Equivalent grams of CO <sub>2</sub> with the same global warming potential of a given gas
595	(·) <sub><i>y</i></sub>	Relative to year <i>y</i>
	EOL	End of life
	EVOE	Environmental value of energy
	FSS	Future societal savings
	GFRP	Glass-fiber reinforced plastic
600	GHG	Greenhouse gas, i.e. CO <sub>2</sub> , CH <sub>4</sub> , NO <sub>2</sub> , F-gases, among others
	IOE	Impact of energy
	LCA	Life-cycle assessment
	LCOE	Levelized cost of energy
	LVOE	Levelized value of energy

605	NEVOE	Net environmental value of energy
	NVOE	Net value of energy
	SCC	Societal cost of carbon
