**Abstract.** In contrast to the multitude of ~~calculation~~-models in the literature for the calculation of rolling contact fatigue in rotating bearings, literature on oscillating bearings is sparse. This work summarizes the available literature on rolling contact fatigue in oscillating bearings. Publications which present various theoretical models are summarized and discussed. A number of errors and misunderstandings are highlighted, information gaps are filled, and common threads between publications are established. Recommendations are given for using the various models for any oscillating bearing in any industrial application. The applicability of these approaches to pitch and yaw bearings of wind turbines is discussed in detail.

## 1 Introduction

While most bearings in industrial applications rotate, there are some notable ones which are required to oscillate. These include bearings in helicopter rotor blade hinges (Tawresey and Shugarts, W. W., Jr., 1964; Rumbarger and Jones, 1968), cardan joints (Breslau and Schlecht, 2020), offshore cranes (Wöll et al., 2018), and blade and yaw bearings in wind turbines, shown in Fig. 1. Blade bearings turn (“pitch”) the blade around its longitudinal axis to change the ~~windblade~~’s angle of attack ~~as it acts on the blade~~. ~~Movements in modern~~ Their movements in modern wind turbines mostly consist of small (typically<sup>1</sup>  $\varphi < 10^\circ$ , often as small as  $\varphi < 1^\circ$ , cf. Stammer et al. (2020)) oscillations with the occasional 90degree-° movement to bring the turbine to a halt. Similarly, yaw bearings rotate the turbine to face into the wind. Their movements are typically fewer and, depending on the site and the yaw system design, longer ( $< 10^\circ$  during power production but potentially more while idling) while they do not tend to become as low ( $\varphi < 1^\circ$ ) as pitch angles (Wenske, 2022).

Rolling ~~bearings-under~~ contact fatigue is a possible failure mechanism of bearings. It is caused by the fact that, even under a constant external load, movement of the bearing (rotation or oscillation) causes movement of the rolling bodies (balls or rollers) relative to the bearing rings. If the rolling bodies transmit load to the raceway, their movement leads to stress cycles, because every location of the raceway changes from a loaded state while it is in contact with a rolling body to an unloaded one while it is not (cf. Fig. 6, left hand side, for a typical case in a rotating bearing). The resulting stress amplitudes can, over time, cause fatigue damage on the raceways, or, less frequently, the rolling bodies. The driving stress for rolling contact fatigue is typically considered to be shear stress. Fatigue can be initiated from shear stress below the surface of the raceway (subsurface fatigue) and

---

<sup>1</sup>See Fig. 3 for amplitude definition.

from shear stress at its surface (surface fatigue) (Lundberg and Palmgren, 1947; Ioannides et al., 1999; Harris and Kotzalas, 2007; Zaretsky

25

Rolling bearings under oscillatory movements are commonly associated with wear damage to the raceways and rolling bodies (Behnke and Schleich, 2022; Stammer, 2020; Grebe, 2017; FVA, 2022b; de La Presilla et al., 2023). In some (Grebe, 2017; Stammer, 2020), small oscillation amplitudes are generally seen to be a risk factor for wear, particularly in grease lubricated bearings (Behnke and Schleich, 2022). However, wear can also be prevented by a number of measures (Schwack, 2020; Wandel et al., 2022) and it is definitely possible for rolling contact fatigue to occur without wear<sup>2</sup> even for oscillating amplitudes as low as  $\theta = 1^\circ$  ( $\varphi = 2^\circ$ ). Rolling contact fatigue, on the other hand, is always a possible failure mechanism even in a properly designed bearing (Sadeghi et al., 2009), except for very low loads (Ioannides et al., 1999), at which there is dispute about its occurrence (Zaretsky, 2010). In many cases, such as large ~~amplitudes, varying amplitudes, oscillation amplitudes,~~ or the use of oil lubrication, wear is unlikely to occur and thus, rolling contact fatigue becomes ~~more relevant. Engineers should consider both types of damage~~ a more important focus. Moreover, depending on its severity, wear in itself doesn't necessarily cause a complete failure of the bearing but it can also accelerate rolling contact fatigue (FVA (2022a, b). Engineers should therefore consider both wear and rolling contact fatigue as a possible failure mechanism ~~and ensure they do not cause a failure of the bearing~~. This paper reviews calculation approaches to determining the rolling contact fatigue life of oscillating bearings. There are a number of approaches for rolling contact fatigue life calculation in the literature, see Sadeghi et al. (2009) and Tallian (1992) for an overview, but they are mostly intended for rotating applications. While any of these could in principle be changed to be used in oscillating applications, this paper collates all approaches that have explicitly been developed for oscillating bearings in general, or that are concerned with specific bearings which oscillate, such as pitch bearings.

30

35

40

As part of the introduction, phenomena which are present in oscillating bearings but not in rotating ones are discussed in Sec. 1.1. An overview of calculation approaches is ~~shown given~~ in Section 2. It includes three different commonly used ISO-based factors (Harris, Rumbarger, and Houpert), all of which have been designed for oscillations with a constant amplitude, and a number of other approaches described in the literature. Section 3 gives an overview of experimental results and Section 4 then discusses when to apply these methods, with an example explaining their applicability to pitch and yaw bearings, which oscillate with a varying amplitude.

45

## 1.1 Operational conditions of oscillating bearings

50

Most operating conditions of oscillating bearings are similar to those of rotating bearings, and much has been written about these conditions. Similarities include the load distribution among the rolling elements, which tends to spread as a function of the radial and axial load (Harris and Kotzalas, 2007) and the bending moment, if present. Individual rolling elements experience point or line contacts, originally described by Hertz for balls (Hertz, 1882) and later described by other methods for rollers (Reusner, 1977; de Mul et al., 1986), resulting in contact pressures on inner and outer ring that tend to be different. The raceways experience cyclic loading, which can cause rolling contact fatigue, often assumed to be caused by shear stress in

55

<sup>2</sup>Discussed in Sec. 3 of this review. The references for which this statement applies use oil lubrication.

**Figure 1.** Wind turbine pitch bearing (green, also called blade bearing) and yaw bearing (blue). ©Fraunhofer IWES/Jens Meier

particular (Lundberg and Palmgren, 1947; Harris and Kotzalas, 2007). There can be grease and oil lubrication present (Hamrock et al., 2000), raceway surface quality and lubrication contamination affects the bearing (Ioannides et al., 1999), and so on.

60 Since this review focuses on oscillating bearings, some differences between rotating and oscillating bearings are, however, worth pointing out. One main difference is simply the travel that a bearing performs when it oscillates as compared to when it rotates: For an oscillation as depicted in Fig. 3, an oscillation arc  $A$  is covered. This is typically smaller than the  $360^\circ$  covered during a rotation. Therefore the life of an oscillating bearing, if measured in oscillations, tends to be bigger than that of an otherwise identical bearing that rotates, measured in revolutions.

65 One commonly discussed difference is the fact that, for small oscillation angles, only part of the raceway may be loaded. For the bearings depicted in Fig. 4, the bearing on the left side only sees cyclic loading on selected locations of its ring, whereas the bearing on the right side sees loading all over its ring, which is distributed unevenly. In Fig. 2, the blue oscillation pattern (“stochastic”) causes the entire ring to experience an uneven number of load cycles, depicted in the right of the Figure. The red pattern on the other hand leads only leads to stress cycles in selected locations, exactly like the left part of Fig. 4. All of the aforementioned cases are fundamentally different from a rotating bearing, in which for both inner and outer ring, every location of a ring experiences the same amount of stress cycles if the bearing is rotated for long enough.

70 Although the stress cycles are evenly distributed on each ring of a rotating bearing, the load is not. It is typically assumed to be constant with respect to one ring, the so-called stationary ring, while the other one rotates relative to it. If the load distribution is uneven, such as the load distribution shown in the top of Fig. 5, this causes the stationary ring to always experience its highest load in the same location. The rotating ring, on the other hand, will have all of its circumferential locations see stress cycles as shown in the bottom of Fig. 5, with only a time shift between the loading of each circumferential location of that rotating ring.

75 For an oscillating bearing, the stationary ring is loaded similarly (identical, if one ignores the fact that there is a discrete amount

of rolling elements), but the rotating ring is loaded differently over time: All of its circumferential positions can experience a very different stress cycle history as shown in Fig. 5 for a small and large oscillation amplitude  $\theta$ .

80 From a viewpoint of rolling contact fatigue, it is also noteworthy that the stress cycles experienced by the raceway are not identical in an oscillating and a rotating bearing. For a rotating bearing, the left of Fig. 6 shows the typical type of shear stress loading history as assumed in the literature (Lundberg and Palmgren, 1947; Harris and Kotzalas, 2007). The center figure shows that at reversal points of the oscillation, the amplitude of the shear stress can be lower than in a rotating bearing (blue case), and thereafter, the sign of the shear stress cycle flips (red case). For small oscillations, the right part of Fig. 6 shows that the oscillation amplitude of a rotating bearing may even never be reached.

85 Aside from these effects that concern the stress cycle history and its distribution over the circumferential locations of inner and outer ring, lubrication is well known to behave differently in an oscillating bearing as compared to a rotating one, causing a time- and movement-dependent film thickness (Venner and Hagmaier, 2008). As discussed above, this can cause wear if bad enough, but even if no wear occurs, different lubricant film thickness than in a rotating bearing may be present.

## 2 Existing calculation approaches

There are a number of publications on the issue of rolling contact fatigue in oscillating bearings. Most of them are based on ISO (ISO, d, c, a, b) or closely related to the model used for ISO. These publications are summarized in Sec. 2.1. Several approaches that have little relation to ISO and its foundations have also been proposed, and are discussed in Sec. 2.2. Some of the ISO-related methods are intended for constant oscillation amplitudes as depicted red in Fig. 2, where an oscillation with a constant amplitude about a position of  $0^\circ$  is shown<sup>3</sup>, while some other ISO-related methods and all non-ISO related methods are intended for arbitrary movement as depicted blue in Fig. 2.

### 95 2.1 ISO-related approaches

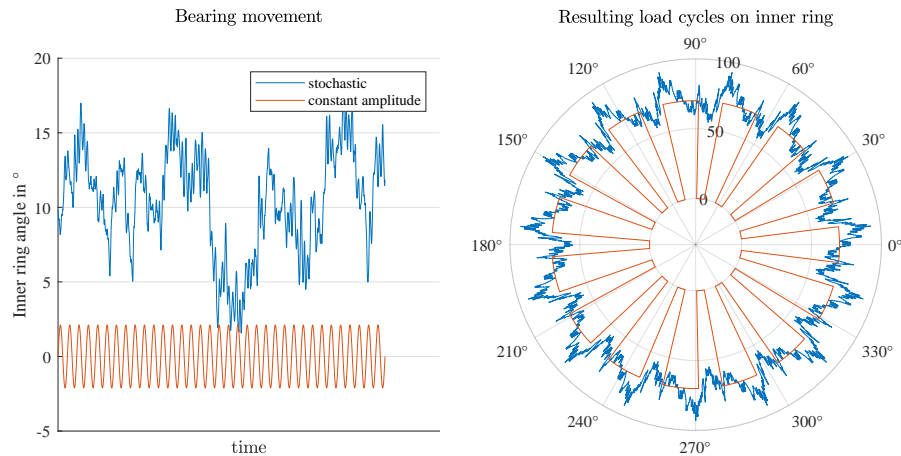

Fundamentally, rolling contact fatigue in oscillating applications is caused by a rolling element repeatedly rolling over locations on a raceway, as is the case in rotating applications. For this reason, many researchers have sought to adapt the well-known ISO approach for rolling contact fatigue calculation to oscillating applications. All of these approaches are hence characterized by the fact that they are based on Lundberg and Palmgren (1947), who proposed that

$$100 \ln \frac{1}{S} \propto \frac{\tau_0^c N^e}{z_0^h} V, \quad (1)$$

where  $S$  is the survival probability,  $\tau_0$  is the maximum orthogonal shear stress and  $z_0$  its depth under the raceway surface at which  $\tau_0$  occurs,  $N$  is the number of load cycles (rollovers), and  $V$  is the loaded volume (Lundberg and Palmgren, 1947, 1952; Harris and K

---

<sup>3</sup>Rolling contact fatigue is driven by relative movement of one of the rings to the other, which means that the mean position of the oscillations in Fig. 2 only moves the position where load cycles occur on the raceway but has no effect on the life of the bearing. The critical difference between the blue and red lines is their relative movement, not their absolute position.

**Figure 2.** Load cycles resulting from oscillation and stochastic movement in a bearing with  $Z = 15$  rolling elements.

Lundberg and Palmgren used Eq. 1 to derive their well-known life equation  $L_{10,rev} = (C/P)^p$ , with dynamic load rating  $C$  and dynamic equivalent load  $P$ , which remains the basis for ISO 281 (ISO, d) and ISO/TS 16281 (ISO, c) as well as countless other publications. They assumed the bearings to be rotating.  $L_{10,rev}$  then gives the number of millions of revolutions at which 10% of bearings are expected to suffer the first visible raceway damage<sup>4</sup>, also called “basic rating life”. In principle, their derivation can be adapted for use in oscillating movement as well. This section discusses publications which either apply or derive such adaptations of the original Lundberg-Palmgren approach, or approaches very similar to it but also based on Eq. 1. Most of these approaches derive corrective factors  $a_{osc}$  that are intended to be applied to a life measured in revolutions and convert it into a life measured in oscillations, i.e.,

$$L_{10,osc} = a_{osc} L_{10,rev}, \quad (2)$$

where  $L_{10,osc}$  is the life measured in oscillations and  $L_{10,rev}$  is the life in revolutions. This equation applies to all so-called “oscillation factors” in this paper. For small oscillation amplitudes,  $a_{osc}$  typically becomes very large, with  $a_{osc}$  commonly (but not always) being in the range of 1...1000. All factors  $a$  in this paper are instances of  $a_{osc}$  as shown in Eq. 2.

There are two possible common definitions of an oscillation “amplitude”; this paper mainly uses  $\theta$  as defined in Fig. 3. Some equations are also given in terms of the double amplitude  $\varphi$  if there are differences to the equation in terms of  $\theta$ . For small oscillation amplitudes, much of the existing literature will predict a high likelihood of wear, particularly for grease-lubricated bearings (Behnke and Schleich, 2022; Stammer, 2020; Grebe, 2017; FVA, 2022b). Nonetheless, as discussed in Sec. 3 of this review, it is definitely possible for rolling contact fatigue to occur without wear<sup>5</sup> even for oscillating amplitudes as low as  $\theta = 1^\circ$  ( $\varphi = 2^\circ$ ).

<sup>4</sup>Or rolling element damage as per ISO 281(ISO, d); strictly speaking this is not included in the derivation by Lundberg and Palmgren (1947) but ISO included it in the definition of life, presumably because it rarely occurs anyway.

<sup>5</sup>The references for which this statement applies use oil lubrication.

### 2.1.1 Harris: Traveled distance

The Harris factor<sup>5</sup> is given in various editions of *Rolling Bearing Analysis* by Harris (Harris, 2001; Harris and Kotzalas, 2007). It considers the effect whereby an oscillating bearing will, depending on the oscillation amplitude, experience a different number of stress cycles on the rings than a rotating bearing. The factor can be interpreted as a conversion of traveled distance into an equivalent number of rotations. For the angle definition in Fig. 3, the total traveled arc  $A$  during one oscillation amounts to  $A = 4\theta$  ( $= 2\varphi$ ). The Harris factor is then simply

$$a_{\text{Harris}} = \frac{360^\circ}{A} = \frac{90^\circ}{\theta} \left( = \frac{180^\circ}{\varphi} \right). \quad (3)$$

Thus, taking an exemplary bearing that oscillates with an amplitude of  $\theta = 10^\circ$  and that, if it were rotating, would have a life of  $L_{10,\text{rev}} = 1$  million revolutions, and applying Eq. 2 and Eq. 3 gives a life of  $L_{10,\text{osc}} = \frac{90^\circ}{10^\circ} L_{10,\text{rev}} = 9$  million oscillations according to the Harris factor. This is because it will execute an arc of  $A = 40^\circ$  per oscillation, which is considered as  $1/9^{\text{th}}$  of a rotation by the Harris factor.

Several references (e.g., IEC (2019)) recommend the use of a so-called load revolution distribution (LRD) or load duration distribution (LDD) for rotating bearings. LRDs sum the number of revolutions at a given load. It is possible to use this approach for oscillating bearings, too, if oscillations are summed and equated to one revolution for every  $360^\circ$  of movement. Doing so is in principle identical to using the Harris factor, if the Harris factor is used to sum up movement independently at each of the same load cases. For a constant rotational speed, LDDs are identical to LRDs; for varying speeds they are merely an approximation.

The Harris factor can be seen as a simplification that neglects two-separate-various effects which may occur in oscillating bearings as opposed to rolling ones. It In particular, it does not take account of the fact that the load distribution on the moving ring over time is different in an oscillating bearing, a fact originally taken into account by Houpert (1999), nor that only part of the raceway may be loaded<sup>6</sup>, originally described by Rumbarger and Jones (1968). A combination and correction of some of the errors in the two aforementioned approaches has been proposed by Breslau and Schlecht (2020) as well as by Houpert and Menck (2021). These approaches are discussed in the following sections.

### 2.1.2 Rumbarger: Partially loaded volume

The Rumbarger effect<sup>7</sup> was originally introduced by Rumbarger and Jones (1968) as early as 1968. This original publication, which has been described as “complex and impracticable” (Breslau and Schlecht, 2020), was then simplified in Rumbarger

<sup>5</sup>This approach has also been referred to as “Harris 1” in some publications (Schwack et al., 2016; Schmelter, 2011; FVA, 2021; Wöll et al., 2018) to distinguish it from the Rumbarger effect (cf. Sec. 2.1.2), which they falsely attribute to Harris, thus denoting it “Harris 2”.

<sup>6</sup>More generally: that there may be a difference in the number of stress cycles for different circumferential locations of the rings, as shown in Fig 2, right. However, Rumbarger only considered differences caused by the fact that some parts of the raceway are unloaded in his publications.

<sup>7</sup>This approach has also been referred to as “Harris 2” in some publications (Schwack et al., 2016; Schmelter, 2011; FVA, 2021; Wöll et al., 2018) due to Harris’s authorship of the NREL DG03 (Harris et al., 2009). Since the earliest publications of this approach in the literature are by Rumbarger, and since Rumbarger was a co-author of NREL DG03, he is credited with the idea here.

**Figure 3.** One oscillation covering arc  $A = 4\theta (= 2\varphi)$  with oscillation amplitude  $\theta$  (and double amplitude  $\varphi$ ) as defined in this paper.

(2003) and NREL DG03 (Harris et al., 2009), but without a derivation of the [simplified approach](#)<sup>8</sup>. Each of these publications introduces an adjusted load rating<sup>9</sup>  $C_{osc}$  for oscillating bearings, and using this in  $L_{osc} = (C_{osc}/P)^p$  gives the life in oscillations. It is possible to introduce an oscillation factor<sup>10</sup>  $a_{osc}$  that produces identical results to the adjusted load rating  $C_{osc}$ , cf. App. A or Wöll et al. (2018). In Appendix A of this paper, the authors include a derivation of the simplified approach and in Appendix B a discussion of inaccuracies and assumptions contained therein.

Aside from the effects also considered by Harris, the Rumbarger effect is based on the assumption that for small oscillation amplitudes, only a part of the raceway may ever be loaded. The loaded volume  $V$  of Eq. 1 and its load cycles  $N$  are then adjusted accordingly, depending on the given oscillation amplitude<sup>11</sup>. Rumbarger does so by defining the angle  $\theta_{crit}$  ( $\varphi_{crit}$ ) as

$$\theta_{crit} = \frac{360^\circ}{Z(1 \pm \gamma)}, \left( \varphi_{crit} = \frac{720^\circ}{Z(1 \pm \gamma)}, \right) \quad (4)$$

where the minus (-) sign refers to the outer raceway and the plus (+) one to the inner raceway, and  $\gamma$  is a common auxiliary factor used in rolling bearing calculations related to the geometry of the bearing<sup>12</sup>.  $\theta_{crit}$  is the oscillation amplitude required to move a rolling element from its initial location on a raceway to that of the next rolling element. Figure 4 shows stressed volumes above and below the critical angle on an inner raceway. The Rumbarger factor as recommended by the authors of this

<sup>8</sup>Breslau and Schlecht (2020) give a more appropriate treatment of this effect by introducing the factor  $a_{osc,2}$  with their Eq. 19-19, which does not contain the simplifications taken by Rumbarger in his simplified approach. This equation was further-simplified-rearranged (without simplifications, but to obtain a less cluttered equation) by Houpert and Menck (2021) into a corrective factor called  $f_{\theta_{crit},i,o}$  in their Eq. 45, here used for the recommended approach. Although Rumbarger uses an adjusted load rating while the other authors use corrective factors, all of these approaches attempt to consider the same effect. The differences arise only because of simplifications in Rumbarger's derivation, cf. Appendices A and B.

<sup>9</sup>Called  $C_{osc}$  in Rumbarger and Jones (1968),  $C_{ao}$  and  $C_{ro}$  for axial and radial bearings in Rumbarger (2003), and  $C_{a,osc}$  in Harris et al. (2009).

<sup>10</sup>Called  $a_{prt}$  in App. A and  $a_{osc_nHa2}$  in Wöll et al. (2018).

<sup>11</sup>The Harris factor, cf. Eq. 3, does not consider that only part of the raceway is loaded for small oscillation angles. Since it merely adjusts the standard (rotation-based) calculation approach by the effect of the difference in traveled distance, it implicitly assumes the same loaded volume as in a rotating bearing.

<sup>12</sup>It is defined as  $\gamma = \frac{D \cos \alpha}{d_m}$ , where  $D$  refers to the rolling body (ball or roller) diameter;  $d_m$  gives the so-called pitch diameter, i.e., the mean of the inner and outer raceway diameters; and  $\alpha$  is the contact angle, where  $\alpha = 0^\circ$  is a purely radial bearing and  $\alpha = 90^\circ$  is a purely axial one.

paper is given by<sup>13</sup> (see Tab. A1 for  $e$ )

$$a_{\text{Rumbarger}} = \begin{cases} \left(\frac{\theta}{\theta_{\text{crit}}}\right)^{1-1/e} \cdot a_{\text{Harris}} & \text{for } \theta < \theta_{\text{crit}}, \\ a_{\text{Harris}} & \text{for } \theta \geq \theta_{\text{crit}}. \end{cases} \quad (5)$$

For  $\theta < \theta_{\text{crit}}$ , only part of the raceway volume is loaded during operation. For this case, Rumbarger (2003) and Harris et al. (2009) give a load rating that is derived in Appendix A. This derivation makes some simplifications, and Appendix B shows the errors that occur when using Rumbarger's derivation. If applied correctly, the factor (or load rating) should shorten the life of a bearing as compared to Harris<sup>14</sup>, though the simplified factor (or load rating) sometimes increases the life for no other reason than the simplifications made in its derivation. The recommendation in form of Eq. 5 is thus based on Appendix A without any simplifications. Note that, since  $\theta_{\text{crit}}$  differs between the inner and outer races, so does  $a_{\text{Rumbarger}}$ . Amplitude  $\theta_{\text{crit}}$  of the outer raceway may be used if a more conservative estimate for the entire bearing is desired<sup>15</sup>.

For values of  $\theta \geq \theta_{\text{crit}}$ , the simplified approach published in Rumbarger (2003) and Harris et al. (2009) is identical to using the Harris factor. This, too, is merely an approximation: Strictly speaking, the life of an unevenly stressed volume (as illustrated in Fig. 4, yellow and blue right hand side) is not the same as that of an evenly stressed volume which occurs in a rotating bearing<sup>16</sup> (identical to Fig. 4, red) an oscillating bearing with  $\theta = \theta_{\text{crit}}$  if the total movement of both bearings is the same). Appendix C proposes an extension of the Rumbarger factor for such situations, but also concludes that the difference in the factor as compared to  $a_{\text{Harris}}$  is almost negligible in most cases. The recommendation in factor chosen for Eq. 5 thus follows the above-mentioned publications.

The Rumbarger effect does not consider the effects of an uneven load zone on the moving ring, which are covered by Houpert. Moreover, it assumes that no slippage of the rolling element set occurs, which would move load cycles to occur on different positions of the ring circumference. For a properly installed bearing, Rumbarger and Jones (1968) demonstrated that this assumption can hold true.

### 2.1.3 Houpert: Load zone effects on the moving ring

The Houpert effect was originally covered by Houpert (1999), with a small error in its derivation. This was corrected by Breslau and Schlecht (2020) as well as Houpert and Menck (2021)<sup>17</sup>. Aside from the effects also considered by Harris, the Houpert

<sup>13</sup>Eq. 5 is identical in terms of  $\varphi$ .

<sup>14</sup>In contrast to the Harris effect, with the Rumbarger effect two competing effects ultimately cause a reduction in life. The loaded volume is lower, which increases life; but the load cycles on that small volume which is loaded are higher, thereby decreasing life. The second effect is stronger and reduces the overall life of the bearing, cf. Eq. A3.

<sup>15</sup>Since the traveled distance of a rolling element contact in the rolling direction  $x$  is identical on the inner and outer raceways, but the outer raceway's circumference is longer than the inner raceway's circumference for contact angles  $\alpha \neq 90^\circ$ , the Rumbarger effect is relatively more detrimental to the outer race: It creates a larger deviation from the loaded volume of a rotating bearing than on the inner ring.

<sup>16</sup>This follows from Eq. 1, where the volume  $V$  has exponent 1 and the stress cycles  $N$  have exponent  $e \neq 1$ .

<sup>17</sup>The two approaches are not completely identical but very similar: Breslau and Schlecht (2020) employ a thorough calculation of the effect only for oscillation amplitudes  $\theta > \theta_{\text{crit}}$ , cf. Section 2.1.2. For a circumferentially loaded ring with oscillating motion, they thus introduce the load integrals called  $J_{\theta_a, \psi}$  and  $J_{\theta_a}$  in their Eqs. 32 and 33. Houpert and Menck (2021) derive an equivalent load called  $Q_{\text{eq}}(\psi)$  in their Eq. 35. This term differs from that derived

**Figure 4.** Rumbarger effect: stressed volume on the inner ring as a function of inner ring angle  $\theta$  relative to  $\theta_{crit,i}$  in a bearing with  $Z=10$  rolling elements.  $\theta_{crit} = \theta_{crit,i}$ , for  $\theta < \theta_{crit}$  and a stationary outer ring  $\theta > \theta_{crit}$ . Part of the Yellow volume experiences zero stress cycles for  $\theta < \theta_{crit}$  is stressed twice per oscillation cycle (cf. For  $\theta \geq \theta_{crit}$  Fig. 3), the entire red volume is stressed four times per oscillation cycle. Black volume is never stressed. Only stress cycles for the inner ring are shown.

185 effect considers that the stress cycle history of the moving ring will be different for an oscillating bearing than for a rotating one. This is illustrated in Fig. 5 for an exemplary element on the moving ring.

In the standard life calculation as pioneered by Lundberg and Palmgren (1947) or used in ISO 281 (ISO, d), the load zone is assumed to be constant relative to one ring (called the stationary ring, typically the outer ring). From the viewpoint of Houpert's considerations, movement of the other ring (rotating or oscillating, typically the inner ring) then does not change  
190 the load distribution of the stationary ring's raceway. This ring is loaded identically for rotating or oscillating operation. Thus,  $a_{Harris}$  gives the correct life of the stationary ring according to Houpert's derivation.

For the moving ring, however, the Houpert effect predicts a different value to  $a_{Harris}$ . Since Harris merely adjusts the standard (rotation-based) calculation approach by the effect of the difference in traveled distance, he implicitly assumes that the effect of the load zone is the same as that in a rotating bearing<sup>18</sup>. Thus,  $a_{Harris}$  implicitly assumes an element as depicted in blue in Fig. 5  
195 moves through the entire load zone once for each  $360^\circ$  of movement<sup>19</sup>. However, in reality this only applies for oscillations where  $\theta = i \cdot 180^\circ$  ( $\varphi = i \cdot 360^\circ$ ),  $i = 1, 2, 3, \dots$ , because for these values of  $\theta$  each element will move around the entire raceway  $2 \cdot \theta = i \cdot 360$  times per oscillation ( $\varphi = i \cdot 360$  times per oscillation). For very small oscillations  $\theta \rightarrow 0^\circ$  ( $\varphi \rightarrow 0^\circ$ ) on the other hand, the elements increasingly converge toward the stress cycle history seen in a stationary ring<sup>20</sup>, see Fig. 5. The Houpert

by Breslau and Schlecht (2020) because they (Breslau and Schlecht) use a calculation approach resembling that of Lundberg and Palmgren (1947) and ISO (d), whereas Houpert and Menck (2021) use an approach close to that used by Dominik (1984). The approach used by Dominik is very similar to that of Lundberg and Palmgren, but uses different sets of equations. These two approaches ultimately give almost identical results if similar empirical exponents (cf. Table A1) are used, but details differ, hence the derivation by Houpert and Menck (2021) includes a term called  $H$  that cancels out whereas that by Breslau and Schlecht (2020) does not.

<sup>18</sup>As does Rumbarger, who uses the same equivalent load for an oscillating ring as for a rotating one in Rumbarger and Jones (1968), and also in Rumbarger (2003), cf. App. A.

<sup>19</sup> $360^\circ$  of movement consisting, for example, of 9 oscillations with  $\theta = 10^\circ$ .

<sup>20</sup>In Houpert's model the stress cycle history of an oscillating ring converges, for small oscillations, against that of a stationary ring in both a rotating and oscillating bearing. These two cases (a stationary ring in a rotating and oscillating bearing) can be considered identical here because Houpert's effect alone, unlike Rumbarger's, does not consider that there are a discrete number of rolling elements in the bearing for the circumferential distribution of load cycles. Rather, he assumes all circumferential locations to experience the same number of stress cycles (with differences in load cycle magnitude only), as is common

factor is generally at or in between the following extreme cases

$$200 \quad a_{\text{Houpert}} = \begin{cases} a_{\text{Harris}} & \text{for } \theta = i \cdot 180 \text{ with } i = 1, 2, 3, \dots \\ & \text{or: purely axial load } (\varepsilon \rightarrow \infty) \\ a_{\text{Harris}} \text{ in a bearing with both rings} & \text{for } \theta \rightarrow 0. \\ \text{stationary relative to load}^{21} & \end{cases} \quad (6)$$

In between these extreme cases, detailed calculations have to be performed, curve fits of which can be found in Houpert and Menck (2021). They depend on a value  $\varepsilon$ , a measure of the load zone size<sup>22</sup>. If applied correctly, the Houpert factor will either be identical to  $a_{\text{Harris}}$  in the above given cases or shorten the life of the bearing in all other cases<sup>23</sup>. The Houpert effect is  
 205 **thus** most noticeable for narrow load zones (small  $\varepsilon$ ) and small oscillation angles  $\theta$ . Houpert and Menck (2021) find deviations which differ by up to 22% from those given by the Harris factor for very narrow load zones and small oscillation amplitudes using ISO exponents (cf. Table A1) and larger deviations of up to 52% using exponents given by Dominik (1984). This is due to Dominik using a higher Weibull slope of  $e = 1.5$ . Houpert and Menck (2021) give curve fits to calculate the Houpert factor<sup>24</sup> for ball and roller bearings. If ISO/TS 16281 (ISO, c) is used for the life calculation, the extreme case of small theta ( $\theta \rightarrow 0$ )  
 210 can be taken into account by assuming both rings are stationary relative to the load and using  $a_{\text{Harris}}$ .

Strictly speaking, the Houpert effect is not independent of the Rumbarger effect, but for its derivations in Breslau and Schlecht (2020) and Houpert and Menck (2021) it is assumed to be.

in a rotating bearing, and integrates over a continuous load distribution around the circumference. This is standard practice for the life calculation of typical rotating bearings and as such also employed in ISO 281.

<sup>21</sup>Both rings being stationary relative to load slightly reduces the life as compared to standard calculations (in which one ring is assumed to be rotating) because it increases the equivalent load of the ring which would otherwise be assumed to rotate. It does not affect the factor  $a_{\text{Harris}}$ .

<sup>22</sup>Common formulae for  $\varepsilon$  in the literature tend to be based on small bearings where the rings can be assumed to be stiff. For bearings with large deflection of the rings, based on e.g., FE simulations, different formulae for  $\varepsilon$  must be used to approximate it, see Houpert and Menck (2021). For multi-row bearings, each row's  $\varepsilon$  must be determined independently. Either the life of each row is then calculated independently and combined into a total bearing life, or the lowest  $\varepsilon$  value is taken as a conservative measure.

<sup>23</sup>It shortens the life in all other cases because, from a viewpoint of rolling contact fatigue, the even distribution of loads over time that is present on a rotating ring is the best case scenario for damage accumulation of a ring. Any oscillation that deviates from this loading causes increasingly more concentrated damage accumulation on selected locations of the ring. Concentrated loading (as present, for instance, on the stationary ring in a typical bearing in most industrial applications) causes a higher equivalent load, and thus a lower life, if all else is equal, than the loading of a ring that rotates relative to the load (Lundberg and Palmgren, 1947; ISO, c). Note that the Houpert effect is, however, expressed through a factor here, rather than by changing the equivalent load.

<sup>24</sup>The reference calls the Houpert factor  $a_{\text{osc}, \dots}$ , and includes in it a corrective factor for the Rumbarger effect, denoted  $f_{\theta\_crit}$ . If only the Houpert factor is desired,  $f_{\theta\_crit} = 1$  can be used for the equations in the reference.

**Figure 5.** Houpert effect: load history of an exemplary element as a function of movement relative to load zone. Small  $\theta$  are similar to no movement, large  $\theta$  are similar to rotation.

### 2.1.4 Other ISO-related approaches and further literature

The above three factors have been covered in a number of publications<sup>25</sup>, and Breslau and Schlecht (2020) as well as Houpert and Menck (2021) present the most up-to-date models which include them. Besides the above given publications, there are a number of additional approaches and applications of the above methods. Since all of the above cases are intended for constant

<sup>25</sup>[A comprehensive list including all publications with relation to the factors, to the best knowledge of the authors, includes: The factors are derived in Rumbarger and Jones \(1968\); Houpert \(1999\); Rumbarger \(2003\); Harris et al. \(2009\); Breslau and Schlecht \(2020\); Houpert and Menck \(2021\), and they are used or discussed in some form in Schmelter \(2011\); Schwack et al. \(2016\); Münzing \(2017\); Wöll et al. \(2018\); FVA \(2021\); Menck \(2023\); Hwang \(2023\).](#)

oscillation amplitudes, some alternative approaches have been developed which are also intended to be usable for stochastic movement, which leads to different load cycles<sup>26</sup> on the bearing rings as depicted in Fig. 2, blue.

220 Menck (2023) generalized the Lundberg-Palmgren method to a discrete model (“The Finite Segment Method”) that can be applied to arbitrary movement. The model applies Eq. 1 to segments of a bearing. The movement of the balls relative to the inner and outer rings for each discrete simulation point are analyzed for potential stress cycles on the respective rings. For each stress cycle  $N$ , the variables  $\tau_0$ ,  $z_0$ , and  $V$  in Eq. 1 are then directly evaluated and the corresponding damage according to the Palmgren-Miner hypothesis is calculated. The individual survival probabilities of all segments can then be combined into raceway lives, which can be combined into a total bearing life. The model thus encompasses previous use cases and includes  
225 the Rumbarger and Houpert effect, but can also be used for arbitrary movement and load histories. Menck (2023) shows the model to produce effectively identical results to ISO 281 for simple use cases which are defined by assumptions identical to those of Lundberg and Palmgren (1947), and reproduces results of oscillating bearings from Houpert and Menck (2021), but also applies the model to a rotor blade bearing of a wind turbine.

230 Hai et al. (2012) propose a generalization of ISO 281 specifically for slewing bearings. They divide the bearing into several segments in a similar way to Menck (2023), but unlike Menck’s, their segment width depends directly on the oscillation amplitude. They also make a number of simplifications not made by ISO 281 or Menck<sup>27</sup>. Their model can be used for individual operating conditions with either rotation or a constant oscillation amplitude; however, several conditions with different amplitudes may also be combined using equivalent loads and equivalent oscillation amplitudes for the segments. They compare their results to an exemplary calculation of NREL DG03 and conclude that their somewhat similar results  
235 validate the method. The simplifications make it impossible to establish whether their method is actually more accurate than simply using the oscillation factors given above.

Schwack et al. (2016) do not present a new model but compare factors from Harris, Houpert, and Rumbarger. They also include an approach denoted “ISO”, which is identical to that of Harris. Having published in 2016, the authors also use the erroneous model of Houpert (1999) that was later corrected (cf. Sec. 2.1.3). Moreover, their application of the Houpert  
240 factor is not recommended for double-row bearings with large structural deformation<sup>28</sup>. Their evaluation of the Rumbarger

---

<sup>26</sup>The term “load cycles” is used here synonymously with “rollovers”. Load cycles in Fig. 2 were determined by using the inner ring angle  $\theta_i$  as depicted on the left-hand side of Fig. 2 (outer ring assumed stationary) to calculate the movement of the cage  $\theta_c = 0.5 \cdot \theta_i \cdot (1 - \gamma)$ . This was then used to obtain relative cage movement on the inner ring  $\theta_{rel,i} = \theta_i - \theta_c$ . A change in  $\theta_{rel,i}$  is then considered a load cycle on the respective position where it occurred.

<sup>27</sup>Because their approach is intended for slewing bearings, they assume the contact ellipse dimensions  $a$  and  $b$  as well as  $z_0$  to be identical on the inner and outer rings; they approximate  $z_0 \approx 0.5b$  and  $\tau_0 \approx 0.25P_{max}$ , which is only completely correct for roller bearings but not ball bearings; they assume the cage moves at half the speed of the rotating ring, which is only true if a purely axial contact of  $\alpha = 90^\circ$  is present; and they assume the critical angle to be identical for the inner and outer rings, using  $\theta_{crit} = 360^\circ/Z$  for both rings.

<sup>28</sup>The publication in question uses a single  $\varepsilon$  value for a large four-point slewing bearing that is based on deformations in Finite Element (FE) simulations. The purpose of  $\varepsilon$  in Houpert’s approach lies in its ability to describe the load zone of a race. Thus, each inner-outer raceway pair should get an  $\varepsilon$  value for a proper calculation, as each of them may have a different load zone. Moreover, determining  $\varepsilon$  based on deformations that occur in FE simulations can be misleading for large slewing bearings, since they tend to have a lot of structural deformation, but common equations given for  $\varepsilon$  are mostly based on assumptions of rigid races. Various suggestions for the derivation of  $\varepsilon$ , including ones for large slewing bearings, can be found in (Houpert and Menck, 2021)

factor<sup>29</sup> results in a longer life than using the Harris factor<sup>30</sup>. As explained in Sec. 2.1.2, this increase only occurs because of simplifications in the derivations performed by Rumbarger but for no physical reason, since the effects considered should shorten the life, not prolong it. The relatively large deviations from  $a_{\text{Harris}}$  shown in Schwack et al. (2016) are therefore both due to inaccuracies in the factors that were used.

245 Wöll et al. (2018) present a “numerical approach” to calculate the life of a bearing subjected to arbitrary time series. Their model evaluates the life of the whole<sup>31</sup> bearing at every discrete time step of the simulation and then calculates the inferred damage according to Palmgren-Miner for every time step, based on the movement that occurred<sup>32</sup>. The model is shown to be identical to a bin count using the Harris factor, cf. Sec. 2.1.1, for simple sinusoidal movements<sup>32</sup>. For a stochastic time series, their numerical approach produces a shorter life than either Harris’s<sup>33</sup>, Rumbarger’s<sup>34</sup>, or Houpert’s approaches applied to a  
250 bin count. Because Wöll et al. (2018) published in 2018, they still use the erroneous Houpert factor from 1999 rather than more recent results, cf. Sec. 2.1.3, hence they obtain a longer life with the Houpert factor even though there is no physical reason for such an increase. Furthermore, they compare a bin count using the approaches of Harris, Rumbarger, and Houpert and obtain results that are higher than those of the numerical approach with all three bin count approaches including Harris, and conclude that using these bin counts “overestimates the lifetime for non-sinusoidal loads and speeds”. It is not possible to assess the  
255 accuracy of this statement because their model is based on the life of the whole bearing and thus also includes simplifications as pointed out by Sec. 2.2 of Menck (2023). They also produce a simple method to calculate an equivalent load for oscillating loads but it fails to take local effects into account as accurately as Menck (2023).

~~Schwack et al. (2016) do not present a new model but compare factors from Harris, Houpert, and Rumbarger. They also include an approach denoted “ISO”, which is identical to that of Harris. Having published in 2016, the authors also use the erroneous model of Houpert (1999) that was later corrected (cf. Sec. 2.1.3). Moreover, their application of the Houpert factor is not recommended for double-row bearings with large structural deformation<sup>35</sup>. Their evaluation of the Rumbarger factor<sup>35</sup> results in a longer life than using the Harris factor<sup>35</sup>. As explained in Sec. 2.1.2, this increase only occurs because~~

---

<sup>29</sup> Called “Harris 2” in the reference.

<sup>30</sup> Called “Harris 1” in the reference.

<sup>31</sup> The fact that Wöll et al. use the *whole* bearing life is the critical difference to Menck’s Finite Segment Method, cf. Menck (2023), Sec. 2.2.

~~<sup>32</sup> One may evaluate the life and the corresponding movement of the bearing as shown in Sec. 2.1.6 with each time step used as a bin, and using only the Harris factor. This is identical to their numerical approach.~~

~~<sup>32</sup> Even though they only show equivalence for sinusoidal movements, one can conclude that their numerical approach is equivalent to usage of the Harris factor for any type of movement if one evaluates the life and the corresponding movement of the bearing as shown in Sec. 2.1.6 with each time step used as a bin, and uses only the Harris factor.~~

<sup>33</sup> Called “Harris 1” in the reference.

<sup>34</sup> Called “Harris 2” in the reference.

~~<sup>35</sup> The publication in question uses a single  $\epsilon$  value for a large four-point slewing bearing that is based on deformations in Finite Element (FE) simulations. The purpose of  $\epsilon$  in Houpert’s approach lies in its ability to describe the load zone of a race. Thus, each inner-outer raceway pair should get an  $\epsilon$  value for a proper calculation, as each of them may have a different load zone. Moreover, determining  $\epsilon$  based on deformations that occur in FE simulations can be misleading for large slewing bearings, since they tend to have a lot of structural deformation, but common equations given for  $\epsilon$  are mostly based on assumptions of rigid races. Various suggestions for the derivation of  $\epsilon$ , including ones for large slewing bearings, can be found in (Houpert and Menck, 2021)~~

of simplifications in the derivations performed by Rumbarger but for no physical reason, since the effects considered should shorten the life, not prolong it. The relatively large deviations from  $a_{\text{HARRIS}}$  shown in Schwack et al. (2016) are therefore both  
265 due to inaccuracies in the factors that were used.

Hai et al. (2012) propose a generalization of ISO 281 specifically for slewing bearings. They divide the bearing into several segments in a similar way to Menck (2023), but unlike Menck's, their segment width depends directly on the oscillation amplitude. They also make a number of simplifications not made by ISO 281 or Menck<sup>35</sup>. Their model can be used for  
270 individual operating conditions with either rotation or a constant oscillation amplitude; however, several conditions with different amplitudes may also be combined using equivalent loads and equivalent oscillation amplitudes for the segments. They compare their results to an exemplary calculation of NREL DG03 and conclude that their somewhat similar results validate the method. The simplifications made make it difficult to establish whether their method is actually more accurate than simply using the oscillation factors given above.

### 2.1.5 Further effects during oscillation

275 Further effects occur during oscillation which are not considered by any of the above approaches.

When a rolling element passes completely over a position on the raceway, the orthogonal shear stress below the surface changes from maximum ( $+\tau_0$ ) to minimum ( $-\tau_0$ ) (Lundberg and Palmgren, 1947; Harris and Kotzalas, 2007). This is the typical stress cycle assumed in all ISO-based approaches mentioned here; it is depicted in Fig. 6 on the left. This ~~load cycle does not take place to the full extent at the outer ends of an oscillation cycle as depicted in Fig. 3.~~ stress cycle history behaves different in oscillating bearings: For raceway positions close to the reversal points of the oscillation, the direction of the load cycles changes; this phenomenon is depicted in Fig. 6 (oscillation, red case). The shear stress of the volume close to the reversal points does not fully span from  $+\tau_0$  to  $-\tau_0$  but is stopped prematurely; this too is depicted in Fig. 6 (oscillation, blue case). Similarly, for oscillations with small amplitudes, the stress range does not extend to the maximum and minimum of a passing contact in rotation, see Fig. 6 (small oscillation). None of these effects is considered in the ISO-based approaches (all approaches covered in Sec. 2.1) named herein.  
285

Lubricant film quality is well known to have a significant impact on rolling contact fatigue life (Ioannides et al., 1999; Harris and Kotzalas, 2007). The thickness of the lubricant film is affected by oscillation, and may even become so poor that wear rather than fatigue becomes the dominant damage mechanism. Numerous studies investigate wear phenomena in oscillating bearings; for a review, see de La Presilla et al. (2023). As far as the authors are aware, there are no simple models to estimate the thickness of the  
290 lubrication film as a function of the oscillation and thus determine its potential effects on rolling contact fatigue. Such an Most bearings are grease-lubricated (Lugt, 2009), including most pitch and yaw bearings (Becker, 2011; Wenske, 2022). Grease consists of, among other things, thickener and base oil (Lugt, 2009). Film thickness estimation would likely become even more

<sup>35</sup>Because their approach is intended for slewing bearings, they assume the contact ellipse dimensions  $a$  and  $b$  as well as  $z_0$  to be identical on the inner and outer rings; they approximate  $z_0 \approx 0.5b$  and  $\tau_0 \approx 0.25P_{\text{max}}$ , which is only completely correct for roller bearings but not ball bearings; they assume the cage moves at half the speed of the rotating ring, which is only true if a purely axial contact of  $\alpha = 90^\circ$  is present; and they assume the critical angle to be identical for the inner and outer rings, using  $\theta_{\text{crit}} = 360^\circ/Z$  for both rings.

**Figure 6.** Left: load cycle as assumed by all ISO-based approaches; other examples: further types of load cycles not considered in ISO.

challenging with grease lubrication due to the effect of the thickener. Therefore, the effect of lubrication is mostly ignored in all models [for rolling contact fatigue calculation in oscillating bearings](#) of which the authors are aware. This statement also  
 295 applies for the non-ISO based approaches discussed in Sec. 2.2.

### 2.1.6 Binning [for oscillating bearings](#)

Life calculations often need to be performed for operating conditions that vary over time. ~~The~~ [As argued in Sec. 2 of Menck \(2023\), the](#) most accurate way to calculate the rolling contact fatigue life of a bearing under varying operating conditions according to the assumptions in Eq. 1 made by ISO-related approaches is to use the Finite Segment Method according  
 300 to Menck (2023); ~~because it~~. [This is because the Finite Segment Method](#) considers local load changes rather than summing global, location-independent bearing damage over time. For most users, it will however be simpler to remain closer to existing approaches that are based on  $C$  and  $P$  and do not require a more detailed calculation approach with local damage calculation. Doing so for oscillating bearings necessitates the use of bins [representing similar operating conditions](#) in combination with oscillation factors (Harris, Houpert, or Rumbarger). This is the most commonly recommended approach, a version of which is  
 305 also found e.g., in the NREL DG03 (Harris et al., 2009). Using bins is merely an approximation ~~;~~ [when compared to a proper application of Eq. 1 \(cf. Menck \(2023\)\). It is an approximation](#) since the aforementioned factors have all been developed for constant oscillation amplitudes around the same mean position and they all assume there is a constant load acting on the bearing as it moves, along with a number of other assumptions made by Lundberg and Palmgren (1947), [resulting in the life of a whole bearing, a process in which local information is lost](#).

310 To apply oscillation factors, movement such as depicted in the stochastic case of Fig. 2 must be translated into bins of oscillations. Typically, variable load is taken into account in fatigue calculations by using rainflow counting (ASTM, 2017) [for classical fatigue of structural components](#). Rainflow counting is also used for the bearing movement (as opposed to the load)

for the life calculation of pitch bearings in NREL DG03<sup>35</sup>, Menck et al. (2020), and Keller and Guo (2022).<sup>36</sup> Performing a rainflow count will provide the bins required for further calculations.

315 The load acting on the bearing is irregular and must be simplified into a single equivalent load  $P$  for each bin of the cycle count. Ideally, to this end, the equivalent load  $P_i$  per time step  $i$  is determined and the equivalent load over the bin  $P_m$  is determined from all time steps  $i = 1 \dots n$  in the bin as per

$$P_m = \left( \frac{N_1 P_1^p + N_2 P_2^p + \dots + N_n P_n^p}{N_1 + N_2 + \dots + N_n} \right)^{1/p} \quad (7)$$

320 ~~This approach is not specific to oscillation and can similarly be found in various bearing manufacturer catalogs and basic machine element text books (Schaeffler Technologies AG & Co. KG, 2019; Liebherr-Components AG, 2017; Roloff et al., 1987; Decker, 1995; Haberhauer and Bodenstein, 2001; Liebherr-Components AG, 2017; Schaeffler Technologies AG, 2019).~~  
~~The value  $N_i = n_i \cdot \Delta t_i$  here represents the distance covered in the condition  $i$  (measured in degrees or revolutions), and can be calculated from the speed  $n_i$  and the time  $t_i$  in that condition<sup>37</sup>. The exponent  $p$  is given in Table A1. The approach in Eq. 7 is not specific to oscillation and can similarly be found in various bearing manufacturer catalogs and basic machine element text books (Roloff et al., 1987; Decker, 1995; Haberhauer and Bodenstein, 2001; Liebherr-Components AG, 2017; Schaeffler Technologies AG, 2019).~~

325 ~~~~~  
 If it is not possible to determine  $P_i$  for each time step, potentially due to the calculation being too costly, it is possible to apply Eq. 7 to the force and moment components making up  $P$  (including radial force  $F_r$ , axial force  $F_a$ , and bending moment  $M$ ) and to then determine  $P_m = f(F_{r,m}, F_{a,m}, M_m)$  from ~~their values~~ a suitable function<sup>38</sup>  $f()$  based on their values  $F_{r,m}, F_{a,m}, M_m$  for each bin (calculated as per Eq. 7, but using  $F_r, F_a, M$  instead of  $P$ ).

330 Using the  $P_m$ -values of each bin, it is now possible to calculate the life of each bin  $L_{rev} = (C/P_m)^p$ . The life in oscillations  $L_{osc}$  according to Eq. 2, using the appropriate factor as determined on the basis of Sec. 4, can be determined too.

All of the bins  $b = 1 \dots B$  obtained are then typically combined into one final life using the Palmgren-Miner hypothesis ~~according to~~ (cf. also Zaretsky (1997); Kenworthy et al. (2023)) according to

$$L = \frac{\phi_1 + \phi_2 + \dots + \phi_B}{\frac{\phi_1}{L_1} + \frac{\phi_2}{L_2} + \dots + \frac{\phi_B}{L_B}} \frac{1}{\frac{\phi_1}{L_1} + \frac{\phi_2}{L_2} + \dots + \frac{\phi_B}{L_B}}, \quad (8)$$

335 where  $L_1, \dots, L_B$  ~~denotes~~ denote the life in bin  $b$ . This may be either the life in oscillations, revolutions, or time. Typically, the life would be in oscillations if oscillation factors have been used but it may be converted to time or revolutions.  $L$  denotes the

<sup>35</sup>Misspelled as “rainbow cycle” in the reference.

<sup>36</sup>For damage mechanisms like wear, where the order of movement is important, Stammler et al. (2018) recommend range-pair counting. In fatigue calculations, rainflow counting is more useful because it can fully represent the effect of a large movement (or load cycle) that is interrupted by many small ones. However, this effect is only noticeable in rolling contact fatigue calculations if the Houpert effect is considered. Otherwise a range-pair count will produce a very similar result to a rainflow count. This is because oscillation cycles of the moving ring in rolling contact fatigue are different from a load cycle: The load cycles are caused by the rolling elements rolling over the raceway and are thus very local phenomena that are seldom interrupted.

<sup>37</sup>Strictly speaking, this equation only applies for a constant load direction, but it can be used as an approximation with some variations in the load direction, too, as proposed here. The same applies for Eq. 8. This increases the uncertainty surrounding the calculation result somewhat, which is explored in Sec. 4.4.

<sup>38</sup>Functions  $f()$  for bearings with only radial and axial load components can be found in ISO 281 (ISO, d). Examples of a function  $f()$  for pitch bearings can be found in (Harris et al., 2009; Menck et al., 2020), where the latter publication is to be preferred.

total, combined life of all operating conditions. The variable  $\phi$  ~~then gives the~~ gives the proportion of oscillations, revolutions, or time performed in that bin, ~~It is calculated according to~~

$$\phi_b = \frac{s_b}{s_1 + s_2 + \dots + s_B} \quad (9)$$

340 where variables  $s_1, s_2, \dots, s_b, \dots, s_B$  are the oscillations, time, or revolutions that occurred while in that bin, but must have the same unit as the ~~life.  $L$  denotes the total, combined life of all operating conditions.~~ lives in Eq. 8. It follows that  $\phi_1 + \phi_2 + \dots + \phi_B = 1$ .

It is worth noting that binning is solely used to reduce the number of data points from real-life data or a simulation. Using modern computers, if there is no hardware-specific necessity to reduce the number of data points, ~~the most accurate approach~~  
345 is it is possible to use each single step taken from e.g., an aeroelastic wind turbine simulation or some other data set and treat it as a separate bin to which Eq. 8 is directly applied, rather than processing the steps into a reduced number of bins. ~~This is~~  
From the perspective of a proper application of the Palmgren-Miner rule to a whole bearing, usage of each single step is the most accurate approach. It is thus both easier and less error-prone, as well as more accurate than binning beforehand. In order to account for oscillation effects, it would then be required to consider the larger oscillation cycle (amplitude) that a specific  
350 step is part of and adjust its life based on that, where the step will typically make up a fraction of the complete oscillation.

## 2.2 Non-ISO related approaches

A number of alternative approaches have been developed in recent years, particularly with a focus on blade bearings. Many of these approaches rely on S-N curves that can be determined without testing a complete bearing.

355 Lopez et al. (2019) propose a model for a blade bearing that uses the movement of the bearing as a basis and computes the multiaxial stress-state at the subsurface of the raceway. Loads are obtained from FE simulations using blade root loads from multibody simulations. They apply various multiaxial fatigue criteria and compare the results. They find that IPC control strategies significantly increase the damage inflicted on a bearing compared to CPC due to the increased movement. The lives calculated with the different fatigue criteria are also sometimes very different from each other.

Leupold et al. (2021) segment a bearing and use a reduced Finite Element model in a multibody simulation to determine  
360 the stress on each segment. Using bearing movement from time series they obtain the number and magnitude of stress cycles for each segment. Individual loads are combined using the Palmgren-Miner hypothesis. Unlike almost all literature on rolling contact fatigue, their model is based on Hertzian normal contact pressure rather than subsurface shear stress. However, they note that “fatigue criteria such as Fatemi–Socie (Fatemi and Socie, 1989) or Dang Van (Dang Van et al., 1989) could also be applied” in subsequent work. They obtain empirical values of the cycles to failure used for the Palmgren-Miner hypothesis  
365 from a test of a full-sized blade bearing<sup>39</sup> and an assumed slope of the S-N curve from the literature, ~~and further.~~ Further, they note that “a large number of tests are necessary for reliable results”, but that “currently, not enough tests have been carried out to determine a reliable service life” with their model.

<sup>39</sup>Presumably a bearing of the same type as used for the calculation, though this is not specified in the reference.

Lopez et al. (2019) propose a model for a blade bearing that uses the movement of the bearing as a basis and computes the multiaxial stress state at the subsurface of the raceway. Loads are obtained from FE simulations using blade root loads from multibody simulations. They apply various multiaxial fatigue criteria and compare the results. They find that IPC control strategies significantly increase the damage inflicted on a bearing compared to CPC due to the increased movement. The lives calculated with the different fatigue criteria are also sometimes very different from each other.

Escalero et al. (2023) propose a method for the probabilistic prediction of rolling contact fatigue in multiple-row ball bearings subject to arbitrary load and movement histories. They use a three-dimensionally discretized model of the raceway in which each finite element's individual stress cycle history over time is analyzed using a rainflow count. They use orthogonal shear stress as the governing parameter but note other criteria may be included in the future. The failure probability of the individual elements is determined based on S-N curves obtained from rotating bending specimens and by applying scale factors because of size differences between the specimen and the elements, and because of the conversion from normal to shear stress. All individual element failure probabilities are combined using the Weibull weakest link principle. The authors demonstrate their method for a reference case in which a blade bearing was tested.

Hwang and Poll (2022) propose an approach that is then further detailed in Hwang (2023). The approach is based on one circumferential position of the inner bearing ring denoted "small stressed volume" (SSV). The stress-load-history of different layers below the race at the SSV is analyzed in detail based on the behavior of the inner ring and the load distribution of the bearing. Residual stresses are optionally included in the calculation. For all load cycles that occur, the Palmgren-Miner hypothesis is applied to layers at the SSV. The layer with the lowest survival probability is used to calculate the life of the bearing. To consider the effect of loaded volume, Hwang proposes a simplified method to estimate the loaded volume in the specimens on which his S-N curves are based, and the loaded volume in the bearing, and to correct the bearing life based on this estimation. The model is applied to rotating and oscillating bearings under constant operating conditions. Hwang (2023) further outlines a proposed application of his model to rotor blade bearings that is not carried out in detail.

Escalero et al. (2023) propose a method for the probabilistic prediction of rolling contact fatigue in multiple-row ball bearings subject to arbitrary load and movement histories. They use a three-dimensionally discretized model of the raceway in which each finite element's individual stress cycle history over time is analyzed using a rainflow count. They use orthogonal shear stress as the governing parameter but note other criteria may be included in the future. The failure probability of the individual elements is determined based on S-N curves obtained from rotating bending specimens and by applying scale factors because of size differences between the specimen and the elements, and because of the conversion from normal to shear stress. All individual element failure probabilities are combined using the Weibull weakest link principle (Weibull, 1939). The authors demonstrate their method for a reference case in which a blade bearing was tested (cf. Sec. 3).

### 3 Experimental validation

Despite the large number of theoretical models discussed above, there are only a few published experimental results of fatigue tests on oscillating bearings.

Tawresey and Shugarts, W. W., Jr. (1964) tested approximately 750 oil-lubricated bearings under oscillating conditions closely duplicating those encountered in helicopter rotor blade hinges but failed to produce a logical explanation of their results (Rumbarger and Jones, 1968). Rumbarger and Jones (1968) therefore reanalyzed 388 of these bearings comprising 13 test series of identically sized, caged needle-roller bearings and derived a life calculation approach based on the Lundberg-Palmgren theory, cf. Sec. 2.1.2. They conclude that “the theory of Lundberg and Palmgren is [...] favorably compared with the life tests” and derive an experimental load rating  $C$  that is shown to be within the bounds defined by the relevant standards at the time (then ASA and AFBMA, today ANSI and ABMA) when adjusted for oscillating motion according to Sec. 2.1.2. Further, they specifically conclude that “the life varied inversely to the fourth power of the radial load”, thus giving  $p = 4$ , which is identical to the load-life exponent of Lundberg and Palmgren (1952) for the case of pure line contact, cf. also Table A1. For the 13 test series, they derive Weibull slopes ranging from  $e = 1.13$  to  $3.55$ , with a mean value of  $e = 2.04$ . This is higher than the value of Lundberg and Palmgren (1952) and ISO 281 ISO (d), cf. Table A1, but they also note that “the wide variation in the values of the Weibull slope are well known”, since different bearing tests routinely produce different Weibull slopes, including even the test data of Lundberg and Palmgren (1952) on which the values of ISO are based; and that the higher Weibull slope may be a product of using more modern steels than those used by Lundberg and Palmgren (1952). Despite the tests going as low as an amplitude of  $\theta = 1^\circ$  ( $\varphi = 2^\circ$ ), none of the bearings show evidence of ~~fretting corrosion~~wear<sup>40</sup>, but the failed bearings presented “varying degrees of flaking breakout or spalling which is characteristic of failure in rolling-contact bearings subjected to rotation”.

Halmos et al. (FVA, 2021) use oil-lubricated cylindrical roller bearings for fatigue tests. They obtain rolling contact fatigue for oscillation amplitudes<sup>41</sup> as low as  $\theta = 1^\circ$  ( $\varphi = 2^\circ$ ) ~~equaling  $x/2b = 1$~~ . The final number of fatigue results is too low to compare them against theoretical calculations, but they conclude that “at least for selected amplitudes, the existing calculation approaches [referring to ISO-based approaches] deliver conservative results compared to the experimentally determined lives”.

Münzing (2017) tests seven ball screws with  $\theta = \theta_{\text{crit}}$ . The lubricant is an aviation grease type Aeroshell 33 MS. The test duration is equivalent to the  $L_{10}$  of the ball screws, ~~which Muenzing determines based on the simplified version of the Rumbarger factor found in NREL DG03 (Harris et al., 2009), cf. Sec. 2.1.2, which he modifies<sup>42</sup> to be equal to 1 for  $\theta > 90^\circ$  ( $\varphi > 180^\circ$ )~~. Five out of seven show initial damage on the raceways. As the standard DIN 631 for ball screws defines a minimum size for surface damage to be considered as fatigue damage and this size is not reached, they are assessed as having passed according to the standard.

<sup>40</sup>A common value to compare wear tests on different bearings is the  $x/2b$  ratio (Schwack, 2020). Low values of  $x/2b$  are often used to indicate wear potential (de La Presilla et al., 2023). Using the data given in the reference, the authors determined this test to correspond to  $x/2b \approx 5$ .

<sup>41</sup>The given amplitude equals  $x/2b = 1$ .

<sup>42</sup>The application of the Rumbarger factor in the reference takes place by changing the equivalent load  $P$  as done in other references (cf. Sec. 2.1.2) but his application, including his changes, are equivalent to those described here. The modification to  $a_{\text{Rumbarger}} = 1$  for large amplitudes is presumably the result of a misunderstanding: Münzing claims the NREL DG03 to state that for oscillation amplitudes of  $\theta > 90^\circ$  ( $\varphi > 180^\circ$ ), the influence of the oscillatory movement can be neglected and the life of a continually rotating bearing can be used for an oscillating one. This is not stated in NREL DG03 though, rather, it implies that the life of a rotating bearing and that of an oscillating one are identical in the case of  $\theta = 90^\circ$  ( $\varphi = 180^\circ$ ) only, but not for amplitudes exceeding this value (cf. Harris et al. (2009): “The total stressed volume and number of stress repetitions per cycle are identical to a bearing in continuous rotation when  $[\varphi = 180^\circ]$ ”).

Escalero et al. (2023) propose an approach discussed in Sec. 2.2. They compare their results to the test of a single blade bearing under axial load but obtain no correlation. The failure onset in the bearing could not be established exactly as failure  
430 already had progressed significantly once it was opened.

Hwang (2023) applies his model to rotating cylindrical roller bearings and angular contact ball bearings as well as four-point bearings. He compares his results to tests of 200 radial cylindrical roller bearings (NU 1006, 55 mm outer diameter) and several double-row four-point bearings of 2.4 m diameter. The model deviates from his experimental results by a factor of about 2 to 10, giving a lower estimate than observed in the tests.

## 435 4 Use of the approaches

This section contains recommendations for when to use which approach. Section 4.1 contains a number of general recommendations, Sec. 4.2 and 4.3 discuss some simple illustrative examples, and Sec. 4.4 and 4.5 detail possible uses for a pitch and yaw bearing in a wind turbine.

### 4.1 Recommendations for use

440 A flowchart of when to use which method, based on the underlying modeled physical principles, is given in Fig. 7. Theoretically, the conditions in the flowchart must hold all the time. Practically, it will be sufficient if they hold most of the time. Dashed arrows represent mathematical approximations, which are considered less accurate than exact calculations. For the ISO-related approaches, recommendations are given according to the underlying physical phenomena considered in the derivations as described in this paper. The recommendations herein may therefore deviate from those given by the respective authors.  
445 For the non-ISO related approaches, recommendations generally follow the respective authors since they rely on less widely acknowledged approaches and may therefore be subject to the more individual interpretation of the respective authors. Further comparisons between the approaches are given in Tab. 2.

Generally, the start of the flowchart is given by the “Start” box. If bins are used (cf. Sec. 2.1.6), the “Start bins” box can be used for an approximation. In this case, the condition  $\theta \geq \theta_{\text{crit}}$  applies if all circumferential positions of the ring experience  
450 some stress cycles over all bins<sup>43</sup>.

For general users seeking to apply a life calculation, ISO related approaches are preferred to non-ISO related ones due to their simplicity and the fact that there is much more empirical basis underlying them. In case of an invariant load direction and oscillation amplitude  $\theta$ , various methods are shown in the figure. Among the ISO related ones, that by Menck can be considered to be most accurate, however, it is also complicated to apply. A less accurate (i.e., an approximated) but simpler method will  
455 be most useful for most readers. Among the approximated ISO related methods for an invariant load direction and  $\theta$ , “Bins with Palmgren-Miner” is the recommended approach due to its wide use in many areas. Among the non-ISO related methods,

---

<sup>43</sup>Since the use of bins represents an approximation, there is no more precise wording than “some stress cycles” for this issue. See e.g. Fig. 2, blue, for an example for which  $\theta \geq \theta_{\text{crit}}$  even though individual oscillation amplitudes may be below  $\theta_{\text{crit}}$ . Note that the position of the rolling elements w.r.t. the rings is required for this assessment, not the position of the inner ring,  $\theta_i$ . The position of the rolling elements w.r.t. a stationary outer ring is given by  $\theta_c = 0.5 \cdot \theta_i \cdot (1 - \gamma)$ ; the position of the rolling elements w.r.t. a moving inner ring is then given by  $\theta_i - \theta_c$ .

Table 2 gives an overview of advantages and disadvantages of each method. Since only users with very specific aims will refer to these methods, it is up to readers to take their own decision as to which of these methods, if any, to use.

None of the ISO-related approaches predicts huge deviations from  $a_{\text{Harris}}$  for regular operating conditions. For a rough  
460 estimate, if the desired life is well below that calculated with the Harris approach, it is very likely to pass with the other ISO-  
related approaches, too. For a more precise calculation, narrow load zones or small oscillation angles below  $\theta_{\text{crit}}$  will produce  
the largest deviations from the Harris factor.

For the Rumbarger effect, based on Sec. 2.1.2 and App. A, the flowchart recommends combining this effect with the Houpert  
effect for ~~non-axial~~ non purely-axial loads (i.e., radial and moment loads). This deviates from Rumbarger and Jones (1968),  
465 where the Rumbarger effect is used without consideration of the Houpert effect for radial bearings, and Harris et al. (2009),  
where the Rumbarger effect is used without consideration of the Houpert effect for moment loads, but this recommendation  
is based on the fact that particularly for these cases which represent relatively small load zones  $\varepsilon$ , the Houpert effect is to be  
taken into account<sup>44</sup>.

The flowchart considers the “numerical approach” of Wöll et al. (2018) as well as Hai et al. (2012) to be approximations.  
470 Although Wöll et al. use the approach for a series of stochastic movements and load directions, they also note “the numerical  
approach lacks the capability of taking sophisticated distinctions into account, as [Rumbarger]<sup>45</sup> does with the critical angle  
distinction and Houpert does with comparing the oscillation amplitude to the load zone size”. The reason their method cannot  
consider these local effects is due to the global application of the Palmgren-Miner hypothesis, see Menck et al. (2022), Sec. 2.2.  
Menck’s Finite Segment Method can be seen as a more accurate (but more difficult to implement) version of Wöll’s numerical  
475 approach that considers local effects also seen with Houpert and Rumbarger. Wöll’s numerical approach is also effectively  
identical to a bin count, listed below it in the flowchart. Hai et al. (2012) is listed as an approximation due to the reasons set  
out in Sec. 2.1.

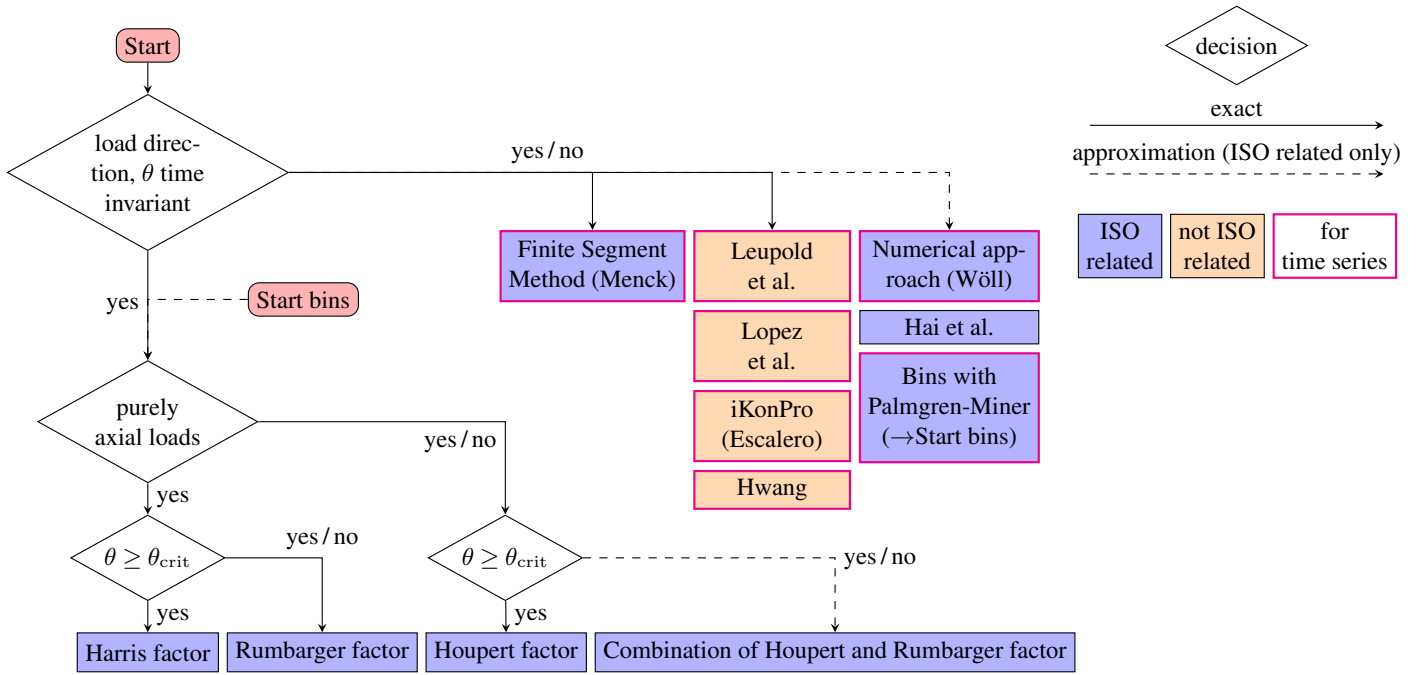

As noted in App. C, the Rumbarger effect actually applies even for oscillation amplitudes  $\theta > \theta_{\text{crit}}$ , but since its effect is so  
small at these amplitudes the effect at larger amplitudes is not considered in Fig. 7.

480 Some approaches are derived in different sources. The authors recommend using the following sources: The Harris factor is  
given in Sec. 2.1.1. The Houpert factor is best considered according to the model of Breslau and Schlecht (2020) or Houpert  
and Menck (2021). The latter reference includes curve fits for ease of use. Older references may be erroneous. The Rumbarger  
effect is best calculated according to Eq. 5 or Breslau and Schlecht (2020) or Houpert and Menck (2021), cf. also Sec. 2.1.2.  
Older references may be oversimplified. A combination of the Houpert factor and the Rumbarger factor is best performed  
485 according to Breslau and Schlecht (2020) and Houpert and Menck (2021). All other approaches in the flowchart are best  
performed according to the publications of their respective authors.

---

<sup>44</sup>This may seemingly contradict the conclusions in Sec. 3, which state that Rumbarger and Jones (1968) already find their results to be consistent with standards despite not considering the Houpert effect. For a radial load giving  $\varepsilon = 0.5$  and small oscillation amplitudes, Houpert and Menck (2021) predict a life reduction of about 10% which would still put Rumbarger and Jones’ results within the range of the standards at the time. This statement therefore does not contradict Rumbarger and Jones’ conclusions.

<sup>45</sup>Called “Harris 2” in the reference.

**Figure 7.** Flowchart to find the simplest applicable life calculation approach for a given oscillating bearing.

**Table 1.** Comparison of different life calculation approaches

Approach	Based on bearing tests or small specimen S-N curves	Considers partial load cycles (cf. Fig. 6)	Considers volume effect	Considers whole race volume	Stress criterion	Experimental validation
ISO-based	bearing	no	yes	yes	$\tau_0$	ok but incomplete
Leupold et al.	bearing	yes	unclear	yes	normal stress $P$ , pot. more	not available
Lopez et al.	S-N	yes	unclear	yes	various	not available
iKonPro	S-N	yes	yes	yes	$\tau_0$ , pot. more	limited data
Hwang	S-N	no	partially	no (only SSV)	various	some deviations

## 4.2 Application to a cardan joint bearing

An exemplary cardan joint connects two shafts whose axes are inclined to each other. The shafts rotate, causing the cardan joint bearing to oscillate with a constant oscillation amplitude of  $\theta = 5^\circ$ . The exemplary bearing is a radial bearing with contact angle  $\alpha = 0^\circ$ . It contains  $Z = 15$  balls with a diameter of  $D = 10$  mm, and has a pitch diameter of  $d_m = 60$  mm. The critical

amplitude according to Eq. 4 is then  $\theta_{crit,o} = 28.8^\circ$  and  $\theta_{crit,i} = 20.6^\circ$  for the outer and inner raceways, respectively. The load zone is made up of a purely radial load that is constant with respect to the outer ring. Half the circumference is loaded, giving  $\varepsilon = 0.5$ , and inner and outer ring osculation are identical.

495 According to In the context of Fig. 7, both the load direction and  $\theta$  are thus time invariant. There is no purely axial load, and  $\theta \geq \theta_{crit}$  does *not* apply. A combination of the Houpert and Rumbarger factors can thus be used by multiplying them as shown in Houpert and Menck (2021), using the Rumbarger factor for the outer race to be conservative. Alternatively, the approach given by Breslau and Schlecht (2020), who discussed cardan joint bearings in their paper in more detail, may be used. Furthermore, the other approaches in the top right of Fig. 7 may also be used since they apply to general time-series based data and thus also apply to simpler data.

500 The Harris factor for this bearing is  $a_{Harris} = 18$  according to Eq. 3. The Rumbarger factor according to Eq. 5 is  $a_{Rumbarger} = 15.1$  if the outer ring is assumed to be conservative; it would be 15.6 for the inner ring. A combination of the Rumbarger and Houpert effect is calculated according to Houpert and Menck (2021) being<sup>46</sup>  $a_{osc} = 14.2$ . This final value is recommended here because it accounts for both relevant effects that occur in the bearing described above. It is smaller than the Harris factor alone, and also smaller than the Rumbarger factor alone, since the effects of both Rumbarger and Harris decrease life.

#### 505 4.3 Application to a crane slewing bearing

An exemplary crane slewing bearing is located at the bottom of a crane which is exclusively used to perform oscillation amplitudes of  $\theta = 90^\circ$  to unload a ship. It is an axial bearing with  $\alpha = 90^\circ$ . The critical amplitude according to Eq. 4 is  $\theta_{crit} = 8^\circ$  for both inner and outer rings. The load is mostly an axial load with only a slight tilting moment component. According to Fig. 7, the load direction is then invariant, and so is the oscillation amplitude  $\theta$ . The load is (approximately) 510 purely axial, and  $\theta > \theta_{crit}$ . Therefore, the Harris factor applies for this bearing. For the amplitude of  $\theta = 90^\circ$ ,  $a_{Harris} = 1$ .

The Rumbarger factor according to Eq. 5 would be equal to  $a_{Harris}$  due to  $\theta > \theta_{crit}$ . The Houpert factor according to Eq. 6 is approximately  $a_{Houpert} \approx a_{Harris}$  due to the mostly axial load giving a large  $\varepsilon \gg 1$ . This is why it is valid to simply use  $a_{Harris}$  for the given case.

515 If  $\theta$  were time invariant, it would also be possible to use the Harris factor and combine different bins using the generalized mean in Eq. 7. Again, more complicated approaches in the top right of the flowchart would also apply.

#### 4.4 Application to rotor blade bearings

A number of publications include rolling contact fatigue calculations for rotor blade bearings, some ISO-related<sup>47</sup>, see Harris et al. (2009); Schwack et al. (2016); Menck et al. (2020); Keller and Guo (2022); Menck (2023); Rezaei et al. (2023), and some

<sup>46</sup>The Houpert factor was calculated using Eqs. 45, 46, 48 and 49 of Houpert and Menck (2021) using the bearing data stated in the above text. Variables  $f_{a_{crit,i}}$  and  $f_{a_{crit,e}}$  in the aforementioned equations account for the Rumbarger effect.

<sup>47</sup>Among the ISO-related publications it is worth noting that NREL DG03 (Harris et al., 2009) is the most common guideline for blade bearing life calculation, and Schwack et al. (2016); Menck et al. (2020); Keller and Guo (2022); Rezaei et al. (2023) are all, at least in part, based on it; only Menck (2023) is not. The publications have not been included in Sec. 2.1 if they merely apply the DG03 but present no new methods or findings relevant to this review.

not, see [Esealero et al. \(2023\)](#); [Hwang \(2023\)](#); [Leupold et al. \(2021\)](#); [Lopez et al. \(2019\)](#); [Lopez et al. \(2019\)](#); [Leupold et al. \(2021\)](#); [Escalero et al. \(2023\)](#).

520 . The non-ISO based methods are, as stated in Sec. 4, best applied according to the respective publications given above, though many of these publications are relatively short and likely not sufficient for an end user to actually copy their technique and apply to an actual bearing. Moreover, according to Sec. 3, the experimental validation for these models is still lacking. Therefore this section will focus on ISO-based approaches, which remain the most common life calculation methods for rolling contact fatigue.

525 Rotor blade bearings typically experience pitch amplitudes as in the stochastic case depicted in Fig. 2: Their oscillation amplitude is irregular, as are the loads acting on the blade in five degrees of freedom. Moreover, the load direction changes slightly, though mostly for smaller loads due to the  $M_x$  component of the bending moment caused by gravitational loads, though for bigger resulting moments,  $M_y$  is driving the direction of the resulting moment (Menck et al., 2020). Therefore, according to Fig. 7, the Finite Segment Method (Menck, 2023) would be the most appropriate ISO-based method for an engineer to use.  
530 However, some simplified approaches exist, too. These include the methods by Wöll et al. (2018) and Hai et al. (2012), and the approach most often chosen by users, a bin count. Using a bin count is likely the most user-friendly and well-known of the approaches. Section 2.1.6 details how to do a bin count and therefore represents the first step required for calculating the life of a pitch bearing, and this step is described in detail below.

At this point we assume bins to be present, where ideally no binning is performed but each time step of the simulation is used as an individual bin (cf. Sec. 2.1.6). Prior to the application of Eq. 8, the lives  $L_b$  of each bin must be calculated using an approach which takes the oscillation into consideration. To this end it is useful to refer to Fig. 7. Although both the load direction and pitch angle  $\theta$  are time invariant, they have to be considered to be approximately constant in order to use oscillation factors, hence the start at “Start bins”. The loads are not purely axial, but the oscillation of the bearing - over the entire operating time of the turbine - is large enough to have rolling elements cover the entirety of the raceway at one point or another<sup>48,49</sup>.  
540 That is to say there is no area that is never stressed, giving  $\theta > \theta_{crit}$ . The Houpert factor is therefore a useful factor to employ, whereas the Rumbarger factor is not, since each segment of the raceway will see rolling elements pass by fairly regularly.<sup>50</sup>

Using ISO/TS 16281, there are two different equivalent loads:  $Q_{ei}$  for the inner ring and  $Q_{ee}$  for the outer ring. For each of these rings, users must decide whether the ring is rotating or stationary relative to the load. Since rotor blade bearings mostly perform small oscillations below approximately  $20^\circ$  of amplitude, an alternative to using the Houpert factor is to use

---

<sup>48</sup>Individual pitch cycles may cover only a small portion of the raceway, but this only causes deviations as large as those given by the Rumbarger factor if this behavior continues for the bulk duration of operation along the same mean position with the same amplitude, which is not the case in a typical pitch bearing.

<sup>49</sup>[The entirety of the raceway is covered by rolling elements if for the largest amplitude  \$\theta\_{max}\$  done by the bearing,  \$\theta\_{max} > \theta\_{crit}\$  is true. Since all pitch bearings perform  \$90^\circ\$  movements \(Burton et al., 2011\) \(corresponding to  \$\theta = 45^\circ\$ \), this is achieved in virtually all pitch bearings: Due to the rolling element diameter being small compared to the pitch diameter \(Wenske, 2022\), pitch bearings commonly have close to  \$Z = 100\$  and more rolling elements and small values of  \$\gamma\$ . This means that for a four-point bearing as used in Menck et al. \(2020\),  \$\theta\_{crit,i} = 2.48^\circ\$  and  \$\theta\_{crit,o} = 2.42^\circ\$ , values which are easily exceeded by a pitch controller even without taking the  \$90^\circ\$  movement into account \(?Bartschat et al., 2023\).](#)

<sup>50</sup>Note that this recommendation is in contrast to the current version of NREL DG03, which uses the Rumbarger effect only (by modifying the load rating - equivalent to using a factor as discussed in Sec. 2.1.2).

545 the equivalent load of a stationary ring for both rings in combination with the Harris factor (cf. Sec. 2.1.3). This is equivalent to the “worst case” scenario of the Houpert factor and is almost identical to it at small oscillation amplitudes.

Figure 8 shows different approaches to calculate the life of a rotor blade bearing using data from aeroelastic simulations. Table 2 summarizes the approaches. The five approaches are ordered with increasing accuracy to the right of the figure, where “increasing accuracy” means that the Palmgren-Miner hypothesis is applied as accurately as possible. All of them are closely  
550 related to ISO and therefore to Eq. 1. The first three approaches (name containing “bins”) all pre-process the time series data into bins based on the bearing movement and load data acting in a given time step. The fourth approach (“stepwise”) uses each individual time step of the simulation as a separate bin. The fifth method (“Finite Segment Method”) does not use binning but directly calculates damage based on the number of rollovers occurring in segments of the ring. This is the most accurate method and can be used as a reference for the others. Results for the first four methods have been obtained using ISO/TS 16281  
555 for the equivalent load. All results are displayed using the Harris factor, if applicable (that is, if bins were used in some form), assuming one ring to be rotating in ISO/TS 16281; and using a more accurate method for oscillation, which means that both rings have been calculated as stationary according to ISO/TS 16281 in combination with the Harris factor. The Finite Segment Method automatically includes effects of oscillation and cannot be used with the Harris factor.

The first three approaches shown in Fig. 8 involve pre-processing into bins. It can be seen that some of their results deviate  
560 more, some deviate less from the Finite Segment Method. These results are heavily dependent on details of the pre-processing used for the data and the results shown here are not representative for other potential types of pre-processing. The fact that the “coarse bins”-simulation using an oscillation correction is so close to the Finite Segment Method is thus likely accidental and not because this particular approach is particularly representative of a more correct method.

Comparing the life  $L_{10,stepwise}$  of the stepwise calculation where one ring is assumed to be stationary and one is assumed to  
565 be rotating (“Harris factor/LRD”) to the results  $L_{10,FSM}$  of the more accurate Finite Segment Method, one can see that

$$L_{10,FSM} = 0.86 \cdot L_{10,stepwise}. \quad (10)$$

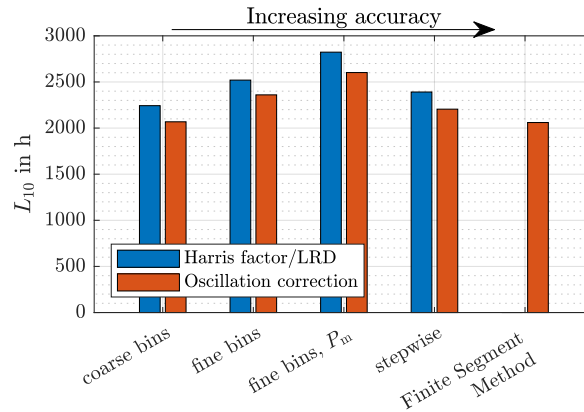

This is roughly in line with using the Houpert factor or assuming both rings to be stationary, which gives a result which is only slightly higher (cf. Fig. 8, stepwise, Oscillation correction). The result of the Finite Segment Method is slightly lower because it first sums local damage over the entire span of the simulation before determining the global bearing life. Therefore,  
570 load concentrations on individual segments and bearing rings are considered more accurately than with the other methods<sup>51</sup>. For calculations performed with ISO-related approaches using binning of data in some form, where one ring is assumed to be stationary and one is assumed to be rotating<sup>52</sup> it is therefore reasonable to expect a life which is 10 to 15% longer than

<sup>51</sup>The result of the Finite Segment Method may thus also be influenced slightly by the Rumbarger effect, i.e., an uneven distribution of rollovers along the circumference, although the effect is much less than would be predicted by the Rumbarger factor if applied directly to the individual pitch cycles. It also captures potential load concentrations on individual raceways because the life of the raceways is determined from their individual segments, therefore including a load history for the raceways too, whereas with the other methods the raceway life is included in a bearing life which is then used for the Palmgren-Miner hypothesis, leading to a loss of information.

<sup>52</sup>This is the standard assumption in virtually all typical rolling contact fatigue life calculations including ISO  
281:281 (Lundberg and Palmgren, 1947; Harris and Kotzalas, 2007; ISO, a).

**Table 2.** Different approaches to calculate the life of a rotor blade bearing

Denomination	Details
coarse bins	1 080 bins with the upper load level per bin used for $P$
fine bins	151 200 bins with the upper load level per bin used for $P$ (Implementation of Menck et al. (2020))
fine bins, $P_m$	Identical to “fine bins” but using generalized mean loads $P_m$ of each bin according to Eq. 7
stepwise	Creates one individual bin per simulation time step
Finite Segment Method	Sums damage from individual rollovers on individual locations of the rings (Implementation of Menck (2023))

**Figure 8.** Comparison of the different approaches in Tab. 2 with Harris factor and additional effects for oscillation considered.

that obtained with more advanced methods. Further deviations that are caused by binning of the data and other forms of pre-processing are impossible to predict and therefore a stepwise calculation is preferable.

#### 575 4.5 Application to yaw bearings

For yaw bearings, the oscillation behavior is highly site dependent. Any wind direction history can be calculated using the Finite Segment Method or the other approaches highlighted with thick borders in Fig. 7. For the design of a wind turbine, yawing movements are seldom simulated, apart from a few design load cases (Wenske, 2022). Rather, constant offsets from

an optimal yawing position are simulated and assumed to be present for a certain amount of operating time. Yaw movement  
580 is then assumed to be distributed among these simulated cases. ~~The design of yaw bearings thus lends itself to binning, since~~  
Since detailed time series will typically not be available, binning will often be necessary in order to calculate the life, though  
detailed time series would be preferable, if available.

Though the behavior is highly dependent on both the site of the turbine as well as the design of the yaw system, some general  
statements can be made. Firstly, even at sites with only one main wind direction, it is likely that this wind direction will vary  
585 by a few degrees. Secondly, the yaw misalignment that triggers a yaw movement is dependent on the yaw system design. Yaw  
misalignments of  $3^\circ$  to  $8^\circ$  are common, realistic values (Wenske, 2022). Finally, the design of large scale yaw bearings, like  
that of pitch bearings, usually includes a large number of rolling elements in excess of 50 or even 100 and more per row<sup>53</sup>,  
giving small critical angles  $\theta_{crit}$ . It is thus unlikely that any yaw bearing will be operated in a manner whereby during the entire  
operating history of the bearing, the loads are truly concentrated only on parts of the raceway, since that would require yaw  
590 movements to be consistently smaller than  $\theta_{crit}$  despite fluctuations in the wind direction and possible slippage of the rolling  
element set. The Rumbarger effect is thus unlikely to be relevant for yaw bearings in the field.

Regarding the Houpert effect, the wind direction is important. Unlike for typical bearings, the rotating (oscillating) ring  
is the one that will always be loaded in one primary position since it is consistently moved toward the wind. The stationary  
ring, on the other hand, can experience very concentrated loads in one position (in the case of a site with only one main wind  
595 direction) or it can even experience loads spread evenly over its circumference (on sites with no clear main wind direction,  
where the wind can come from any direction). In the first case (one main wind direction only), similar to pitch bearings,  
both rings experience a high concentration of loads in one spot. It is thus recommended that the Houpert effect is considered,  
ideally by using the equivalent load for a stationary ring, for the calculation of both  $Q_{ei}$  and  $Q_{ee}$  if ISO/TS 16281 is used.  
Otherwise, the Houpert effect can be taken into account by using the publications mentioned in Sec. 4.1. Assuming one main  
600 wind direction is the more conservative assumption and should be the approach to choose in case of doubt. Since yaw bearings,  
like pitch bearings, are strongly affected by a tilting moment, ~~a~~ each of their raceways is commonly loaded around half of  
its circumference (Chen and Wen, 2012; Schwack et al., 2016; Menck et al., 2020; Graßmann et al., 2023), corresponding to a  
load zone parameter (cf. Sec. 2.1.3) of  $\varepsilon = 0.4 \dots 0.6$ . With this value of  $\varepsilon$ , a life which is around 10% shorter than that obtained  
with the Harris factor is to be expected for small oscillation amplitudes (Houpert and Menck, 2021). If the main wind direction  
605 is truly evenly spread over all compass directions, it is permissible to use the equivalent load of a ring that rotates relative to  
the load for the outer ring, approximately equivalent to simply using the Harris factor for the entire bearing<sup>54</sup>.

---

<sup>53</sup>See footnote 49.

<sup>54</sup>In this example, the behavior of a typical bearing is flipped on its head. Typical bearings in most industrial applications experience concentrated loading  
on the stationary ring, since it is stationary with respect to the load. The rotating ring, on the other hand, sees loads all over its circumference (cf. Fig. 5,  
“rotation”: All elements on a rotating ring are loaded like the example one, only with a time shift.) In a yaw bearing in which the wind comes evenly from all  
directions eventually during the turbine lifespan (for example, 25% of operational time coming from north, 25% from south, 25% from south and 25% from  
west), the outer ring is loaded in all positions at some point and thus experiences similar damage accumulation over its circumference as a rotating ring in  
a typical bearing. This is a very theoretical example to illustrate potential influences of the Houpert effect, in most cases, it will be easier to simply assume  
concentrated loading as discussed above, which is the more conservative case.

## 5 Current challenges and critical future work

610 While there are a number of different approaches for the calculation of rolling contact fatigue in oscillating bearings, the validation of these models is lacking to a large extent. Among the ISO related approaches, some experimental results suggest that the predictions may be accurate, as discussed in this paper. One can also argue that the ISO related approaches, being based on the widely accepted standard ISO 281, are partially validated by the rotating bearings which were used to validate the standard in itself.

615 For regular operating conditions, the ISO related approaches do not differ by a huge margin. Validation of one approach therefore also increases the likelihood that another of the ISO related ones is accurate. Potential attempts to validate these bearings can focus on the different phenomena that are covered by the Houpert and the Rumbarger effect to validate them independently of each other, but as they are based on the same foundation, these validations (if successful) will have a positive effect on each other, too.

A number of publications have shown deviations of rotating bearing lives from the ISO standard (Harris and Kotzalas, 2007; Londhe et al. . A validation of the ISO related models in this paper should therefore take into account that they are relative values. Any bearings used for oscillating tests should ideally also be used for rotating tests in otherwise identical or similar conditions, to ensure that potential deviations from the results shown in this review are not simply due to the bearings themselves lasting longer than suggested by the standard, but actually due to the relative factors given here being inaccurate.

625 All of the models - ISO related and non-ISO related alike - completely neglect the influence of lubrication. This is probably the grossest simplification and the biggest uncertainty underlying all models discussed in this review. Lubrication is a complicated topic that is often simplified. Even for regular bearings, over 90% of bearings are grease-lubricated (Lugt, 2009) but for the life calculation the grease behavior is mostly approximated using base oil properties even though grease is well known to behave differently (Lugt, 2012). For oscillating applications, due to the movement-dependent lubrication film (Venner and Hagneijer, 2008) , this issue becomes much more complex than for rotating bearings, hence why all models in this review simply neglect the topic completely.

630 While this review, and many publications before it (Harris et al., 2009; Schwack et al., 2016; Menck, 2023) applied ISO related methods to large slewing bearings, there have been publications suggesting (without evidence) that the ISO standard does not apply for pitch and yaw bearings bearings (Potočnik et al., 2010; Lopez et al., 2019). Whether or not this is the case is another topic worth researching. The non-ISO related methods in this review present an alternative approach at life calculation for people who distrust the ISO standard, but the evidence proving their aptitude is, to date, lacking to a much greater extent  
635 that that of the ISO related models. While it is possible that large oscillating slewing bearings behave differently than suggested in this review, it is also an option to introduce corrective factors or change load rating and equivalent load in order to perform a standard calculation for large oscillating slewing bearings nonetheless.

## 6 Conclusions

This work has given an overview of the literature on rolling contact fatigue calculation for oscillating bearings. Many approaches are based on ISO, tend to be user friendly, and are often applied in the literature. Most of these approaches have been proposed and used in the literature without an explanation as to when they apply. The aim of this paper was to explain when which approach can be applied. It is worth noting that many older publications, particularly for the Rumbarger effect and the Houpert effect, include errors or simplifications and hence more recent publications, including this one, are to be preferred as a source. When applied correctly according to more recent literature and for standard operating cases, the deviations between Harris, Rumbarger, and Houpert as well as other ISO-based approaches are typically not huge. This also applies to the operating conditions of pitch and yaw bearings. The large deviations obtained with alternative approaches to the Harris factor that are seen in some publications are often due to errors or simplifications. All ISO-based approaches shorten the calculated life compared to the ~~results using the~~ Harris factor (or are identical to it) if applied correctly. This is because all ISO-based approaches that deviate from Harris do so because they either incorporate the Houpert or Rumbarger effect, or both, and both of these effects cause either the same life or a reduction in life compared to the Harris factor if applied correctly. Currently published ISO-based calculation approaches that increase life compared to the Harris factor are erroneous, potentially due to being overly simplified. Some phenomena described in this paper that have not yet been analyzed in the literature could slightly increase lives even for ISO-based methods.

Aside from these commonly used factors, a number of alternative approaches have been discussed. These include some ISO-related ones and some approaches that deviate significantly from ISO. Many of these alternative approaches, including ISO-related and non-ISO-related ones, have been designed particularly for rotor blade bearings.

The experimental validation of all models in the literature is relatively poor. Some experimental results from the ISO-based approaches ~~suggest that their predictions~~ compared well with the calculated life, suggesting that that the predictions of ISO-based methods may be relatively close to the actual life, while validations of the alternative approaches are mostly lacking.

This work may help engineers identify which approach to use for the rolling contact fatigue life calculation for a given oscillating bearing. It has been written with a particular focus on wind turbine slewing bearings, but may also be used as a reference for any other oscillating bearings in other industrial sectors.

*Data availability.* Aeroelastic load time series and FE-simulated bearing loads for the rotor blade bearing calculations in this paper can be found under <https://doi.org/10.24406/fordatis/113> (Popko, 2019) and <https://doi.org/10.24406/fordatis/109> (Schleich and Menck, 2020). All other data is included in this paper.

## Appendix A: Derivation of the Rumbarger factor

Lundberg and Palmgren (1947) state, using Eq. 1 and knowing that  $N = uL$ ,

$$\ln \frac{1}{S} \approx \frac{\tau_0^c (uL)^e}{z_0^h} V, \quad (\text{A1})$$

where  $\tau_0$  is the maximum shear stress and  $z_0$  its depth under the raceway,  $V$  is the loaded volume, and  $u$  gives the stress cycles per million oscillations or revolutions  $L$ . For a constant survival probability  $S$ , it follows that

$$L \approx \left( \frac{z_0^h}{\tau_0^c V} \right)^{1/e} u^{-1}. \quad (\text{A2})$$

Comparing two identical bearings under identical  $\tau_0$  and  $z_0$ , one oscillating and one rotating, for  $\theta < \theta_{\text{crit}}$ , where  $V_{\text{osc}}/V_{\text{rot}} = \theta/\theta_{\text{crit}}$  we obtain

$$a_{\text{prt}} = \frac{L_{\text{osc}}}{L_{\text{rot}}} = \frac{u_{\text{rot}}}{u_{\text{osc}}} \left( \frac{\theta}{\theta_{\text{crit}}} \right)^{-1/e}. \quad (\text{A3})$$

This is equivalent to Eq. 18 given by Breslau and Schlecht (2020). In their Eq. 19, using  $\theta_{\text{crit}}$  from Eq. 4, they then go on to derive<sup>55</sup>

$$a_{\text{prt i,o}} = \frac{Z(1 \pm \gamma)}{4} \left[ \frac{\theta Z(1 \pm \gamma)}{360^\circ} \right]^{-1/e} \quad (\text{A4})$$

with the minus (−) sign referring to the outer and the plus (+) sign to the inner raceway. Using  $a_{\text{Harris}}$  from Eq. 3, this can be rewritten as done by Houpert and Menck (2021)

$$a_{\text{prt i,o}} = \left( \frac{\theta}{\theta_{\text{crit i,o}}} \right)^{1-1/e} a_{\text{Harris}}. \quad (\text{A5})$$

Both Rumbarger and the NREL DG03 (co-authored by Rumbarger) use a different amplitude definition than in this paper, defined by  $\varphi = 2\theta$ . Equation A4 then becomes

$$a_{\text{prt i,o}} = \frac{Z(1 \pm \gamma)}{4} \left[ \frac{\varphi Z(1 \pm \gamma)}{720^\circ} \right]^{-1/e} \quad (\text{A6})$$

$$= \underbrace{(1 \pm \gamma)^{1-1/e} 4^{-1+1/e} Z^{1-1/e}}_{f_{\text{Rum}}} \left[ \frac{\varphi}{180^\circ} \right]^{-1/e}. \quad (\text{A7})$$

The factor  $f_{\text{Rum}}$  is introduced here to include the terms  $(1 \pm \gamma)$  and  $4^{-1+1/e}$ , both of which Rumbarger assumes to be approximately 1. Thus, Rumbarger obtains  $f_{\text{Rum}} \approx 1$ . In order to keep track of the error introduced by this assumption,  $f_{\text{Rum}}$  will be retained in the following equations.

Rumbarger does not adjust life by using a factor, but by changing the load rating. A factor can be converted to an equivalent load rating using

$$L_{10,\text{prt}} = a_{\text{prt}} \left( \frac{C}{P} \right)^p = \left( \frac{a_{\text{prt}}^{1/p} C}{P} \right)^p = \left( \frac{C_{\text{Rum}}}{P} \right)^p \quad (\text{A8})$$

<sup>55</sup>Equations here are adjusted to use degrees rather than radians as done in the reference.

**Table A1.** Exponents  $c, e, h, p$  according to ISO

	$c$	$e$	$h$	$p$
Point contact (ball bearings)	31/3	10/9	7/3	3
Line contact (roller bearings)	31/3	9/8	7/3	4 or <sup>56</sup> 10/3

with Eq. A7 used for the adjusted Rumbarger load rating

$$C_{\text{Rum}} = a_{\text{prt}}^{1/p} C = \left( f_{\text{Rum}} Z^{1-1/e} \left[ \frac{\varphi}{180^\circ} \right]^{-1/e} \right)^{1/p} C. \quad (\text{A9})$$

Equation A9 is identical to the load ratings given in (Rumbarger, 2003) and (Harris et al., 2009) when assuming  $f_{\text{Rum}} = 1$  and using the parameters given in Table A1.

695 The error can simply be corrected by using either Eq. A9 or Eq. A7 separately for each raceway (cf. Breslau and Schlecht (2020)) and without assuming  $f_{\text{Rum}} = 1$ .

## Appendix B: Error of the Rumbarger factor for $\theta < \theta_{\text{crit}}$

By assuming  $(1 \pm \gamma) \approx 1$ , Rumbarger effectively neglects the difference between inner and outer races and obtains an equation which can be used for the entire bearing. The assumption  $4^{-1+1/e} \approx 1$ , on the other hand, is an unnecessary simplification that  
700 leads to errors, as will be seen in the following.

### B1 Error on one raceway

The error of Rumbarger's assumptions for one single raceway can be easily calculated by comparing the life  $L_{10,\text{prt}}$  from Eq. A8 that, correctly, assumes  $f_{\text{Rum}} \neq 1$  to that which approximates  $f_{\text{Rum}} = 1$  as done by Rumbarger.

$$\frac{L_{10,\text{prt}}(f_{\text{Rum}} = 1)}{L_{10,\text{prt}}(f_{\text{Rum}} \neq 1)} = \frac{1}{f_{\text{Rum}}} \quad (\text{B1})$$

705 Values of  $1/f_{\text{Rum}}$  for point and line contact as well as different values of  $\gamma$  are depicted in Fig. B1. One can see that  $C_{\text{Rum}}$  consistently overestimates the actual life, up to 23% for  $\gamma = 0.35$  on a roller bearing's outer ring. The error is dominated by Rumbarger's neglect of the factor  $4^{-1+1/e}$ , which is 0.87 for point contact and 0.86 for line contact. Simply assuming

<sup>56</sup>Exponent  $p = 4$  follows from the given  $c, e,$  and  $h,$  and is consequently used by Rumbarger (2003) as well as Breslau and Schlecht (2020) in their derivations. Nonetheless, ISO 281 uses  $p = 10/3$  in calculating  $L = \left(\frac{C}{P}\right)^p$ . This is explained in (Lundberg and Palmgren, 1952) and (ISO, a), which argue for the choice of  $p = 10/3$  because in some load cases, line contact within roller bearings may turn into point contact. Thus:  $p = 4$  for detailed calculations of rolling contact fatigue where line contact is sure to take place; and  $p = 10/3$  for calculations by general users applying  $(C/P)^p$ .

$\gamma = 0$  thus causes an error of roughly 15% to 17%. Further differences are caused by neglecting  $(1 \pm \gamma)^{1-1/e}$ , which appears reasonable for very large bearings ( $\gamma \rightarrow 0$ ) but less so for smaller ones ( $\gamma \gg 0$ ).

**Figure B1.**  $\frac{L_{10,\text{prt}}(f_{\text{Rum}}=1)}{L_{10,\text{prt}}(f_{\text{Rum}}\neq 1)}$  for inner and outer ring with point and line contact.

## 710 B2 Error for the entire bearing

For the entire bearing, the matter is more complex. Adjusted lives  $L_{\text{prt } i} = a_{\text{prt } i} L_i$  of the inner ring and  $L_{\text{prt } o} = a_{\text{prt } o} L_o$  of the outer one can be combined via

$$L_{\text{prt}} = \left( L_{\text{prt } i}^{-e} + L_{\text{prt } o}^{-e} \right)^{-1/e}. \quad (\text{B2})$$

For an axial bearing with  $\gamma = 0$  giving  $a_{\text{prt } i} = a_{\text{prt } o}$  and  $L_i = L_o$  this can be simplified into

$$715 \quad L_{\text{prt}} = 2^{-1/e} a_{\text{prt } i} L_i. \quad (\text{B3})$$

The relative difference between assuming  $f_{\text{Rum}} = 1$  and  $f_{\text{Rum}} \neq 1$  is then again given by  $L_{\text{prt}}(f_{\text{Rum}} = 1)/L_{\text{prt}}(f_{\text{Rum}} \neq 1) = 1/f_{\text{Rum}}$ , thus giving the same deviations as Fig. B1 for  $\gamma = 0$ . If  $\gamma \neq 0$ , the errors will deviate depending on the specific bearing design.

## Appendix C: Extension of the Rumbarger effect for unevenly loaded volume with $\theta > \theta_{\text{crit}}$

720 For the operational scenario shown in Fig. 4 in yellow on the right hand side, the volume may be separated into volumes  $\psi_1$  and  $\psi_2$  each experiencing one or two stress cycles per half oscillation, with  $\psi_1 + \psi_2 = 360^\circ/Z$ . The corresponding oscillation amplitudes are given by  $\theta_{\psi_1} + \theta_{\psi_2} = \theta_{\text{crit}}$ , where  $\theta_{\psi_2} = \theta - \theta_{\text{crit}}$ . Equation A4 may then be used separately for each of the individual volumes to obtain  $L_{\psi_1} = a_{\text{prt},\psi_1} L$  and the overlapping volume  $\psi_2$  experiencing twice as many cycles, giving  $L_{\psi_2} =$

$\frac{1}{2}a_{\text{prt},\psi_2}L$ . These can be combined via

$$725 \quad L_{\psi_1+\psi_2} = \left( L_{\psi_1}^{-e} + L_{\psi_2}^{-e} \right)^{-1/e} \quad (\text{C1})$$

$$= \underbrace{\left( a_{\text{prt},\psi_1}^{-e} + \left( \frac{1}{2}a_{\text{prt},\psi_2} \right)^{-e} \right)^{-1/e}}_{a_{\text{prt},\psi_1+\psi_2}} L. \quad (\text{C2})$$

This allows for the analysis of the Rumbarger effect for oscillations  $\theta > \theta_{\text{crit}}$  with overlapping volumes. Fig. C1 shows an exemplary calculation of  $a_{\text{prt},\psi_1+\psi_2}$  for a 7220 type bearing normalized to the Harris factor. The result of  $a_{\text{prt},\psi_1+\psi_2}$  can be seen to be almost identical to  $a_{\text{Harris}}$ .

**Figure C1.**  $a_{\text{prt},\alpha+\beta}/a_{\text{Harris}}$  for the inner ring of a 7220 type bearing for  $\theta > \theta_{\text{crit}}$ .

Below, the reply to reviewer 1 (Jonathan Keller) can be found.

Thank you for your review. Answers and comments are found below in blue.

#### General Comments

In this paper, the authors summarize the literature pertaining to rolling contact fatigue life fatigue for oscillating bearings – including many clarifications and filling of gaps. The similarities and differences and pros and cons for the various methods are highlighted, concluding in an interesting and helpful flow chart that recommends the best method(s) depending on the application conditions. This is followed by several different examples that describe the basic parameters of each application from the resulting method. This reviewer’s experience is that the variety of these methods is quite confusing, so having a succinct review of them with a few examples is helpful. The title is certainly sufficient, but I might also suggest “Review of rolling contact fatigue life calculation for oscillating bearings and application-dependent recommendations for use”. It’s a bit more general, as there are 2 non-wind examples, and 2 wind examples.

Thank you for the suggestion, we have changed the title accordingly.

#### Specific Technical Comments

None

#### Minor Clarifying Comments

Line 12: I would add “Their movements...” to indicate to the reader that the sentence is describing pitch movements, as the same language is used in the next sentence to describe yaw movements.

Changed as suggested.

Line 25: I would write “An overview...is given in Section 2.”

Changed as suggested.

Line 168: I believe this is an “s” missing in “...either Harris’s...”

Added an s.

Below, the reply to reviewer 2 (Edward Hart) can be found.

We thank Mr. Hart for the comprehensive review. Answers and comments are found below in blue. Because a lot of changes have been made, please consider that the revised manuscript contains the latest version; some paragraphs have been edited multiple times and the replies given in this document may not be up to date completely.

WES Paper Review:

*Review of rolling contact fatigue life calculation for oscillating bearings and recommendations for use, with examples for wind turbine bearings*

Reviewer: Dr Edward Hart (University of Strathclyde)

17/10/2023

**Summary:** This paper reviews the concepts and methodologies which have been proposed/developed for application in calculating (rolling contact fatigue) rating lives, as well as seeking to provide guidance on when each of the available approaches might be most suitable. The authors additionally seek to provide a unified view regarding how each of these methodologies relate to each other. Specific focus is placed on applications to slewing bearings in wind turbines.

**General comments:** This is an important topic which has arguably received less attention in wind research (and in rolling bearing research more generally) than it should, given the criticality of slewing/oscillating bearings to wind turbine function and reliable operation. The authors demonstrate a very high level of expertise regarding this topic, and the manuscript contains a good number of important contributions to support future research in this topic area as well as the improved application of such techniques in wind research more generally. As a result, this reviewer feels there is a clear contribution to the scientific literature, making a paper on this topic both novel and appropriate for publication in WES. Having said that, the submitted manuscript falls short of what I would consider as being immediately publishable (for reasons which will be outlined). I am therefore recommending that major revisions are undertaken by the authors to ensure the full potential of this valuable paper are realised. At a high level the following points need to be addressed:

1) The writing throughout the paper has a tendency to be imprecise and informal. Clarity and specificity are crucial when seeking to elucidate a complex topic. Extensive improvements to language and the rigour with which concepts are discussed is therefore encouraged to ensure clarity and avoid confusing the reader (specific details are provided under “Specific comments”).

This has been addressed whenever criticized.

2) The paper focuses on slewing bearing in wind turbines, but the introduction/background of the paper does not introduce or outline these bearings in any detail or provide an overview of their design, design trends and load conditions and/or provide information of their failure rates or critical issues as informed by the scientific literature. I believe a more complete background on these bearings is therefore required.

We would say that the paper focuses on oscillating bearings, and the calculations of oscillating bearings are then applied to slewing bearings, among others. The main focus of the paper is a review of existing literature on *oscillating* bearings, which may or may not be slewing bearings. Some people have speculated that large slewing bearings behave differently from small bearings but there is little to no evidence in the literature to support that hypothesis, hence it is not a point that we cover to a great extent in this paper. It will be mentioned in the “current challenges and future work” section, though.

3) Motivation – the introduction appears to indicate that wear is an issue for wind turbine slewing

bearings, before saying that rolling contact fatigue will be the focus of this review. As a result, it feels like the authors undermine their own paper at this stage. Please take more time to elaborate on what we know about failure in these bearings, and to motivate why an analysis of rolling contact fatigue analysis remains important here (as it certainly does). The current exposition of this point feels rushed and underdeveloped.

The introduction comments on potential wear risks of *oscillating* bearings rather than slewing bearings in particular. (cf. above reply to 2))

Unfortunately we don't know a whole lot about failures of oscillating wind turbine slewing bearings, there are not many (if any) publications on failed pitch bearings in the scientific literature; informally through alternative information channels (social media such as LinkedIn) it is possible to find some information on failed pitch bearings but these are often related neither to wear nor to rolling contact fatigue. Rolling contact fatigue is one of the few failure mechanisms that can be calculated with some accuracy and thus it always makes sense to validate that a bearing is designed to withstand it. Moreover, due to the speed in which the wind industry continues to evolve, we would argue that past failures do not necessarily inform future failures, that is, new designs might cause issues that have not yet been observed because the turbines in the relevant MW class haven't been operating long enough. This being a review that focuses on oscillating bearings in general and applies the findings of that review to wind turbine slewing bearings, we don't think this is necessarily the place to discuss this topic.

Slightly changed the introduction to emphasize that RCF can always occur in principle and should be designed against:

Rolling bearings under oscillatory movements are commonly associated with wear damage to the raceways and rolling bodies (Grebe, 2017; Stammer, 2020; Behnke and Schleich, 2022; FVA, 2022; de La Presilla et al., 2023). Wear can set in very quickly, but it can also be prevented by a number of measures (Schwack, 2020; Wandel et al., 2022). Rolling contact fatigue, on the other hand, is always a possible failure mechanism even in a properly designed bearing (Sadeghi et al., 2009), except for very low loads (Ioannides et al., 1999), at which there is dispute about its occurrence (Zaretsky, 2010). In many cases, such as large oscillation amplitudes, or the use of oil lubrication, wear is unlikely to occur and thus, rolling contact fatigue becomes a more important focus. Engineers should therefore consider both wear and rolling contact fatigue as a possible failure mechanism. [...]

4) Structure – I learned many fascinating new concepts while reading this review, in particular the various important effects present in oscillating bearings. However, these new concepts are dotted throughout the paper, only appearing as they are included in one method or another. It makes it very difficult to develop a clear appreciation for the overall operating/loading conditions, complexities and nuances of oscillating bearings when the information is provided in this manner. I would therefore urge the authors to introduce a new section at the start of the paper, along the lines of “Operational fatigue conditions in oscillating bearings” in which all of the critical real world aspects are described and discussed, prior to any consideration of the various fatigue models and which effects they account for. This will provide readers with a clear outline of the “ground truth”, based on which they will be better placed to appreciate all later discussions of the various models and what they do or do not include.

Added a new subsection to the introduction: 1.1 Operational conditions of oscillating bearings

5) Throughout the paper, many complex concepts (e.g. subsurface stress time histories in rolling contact, lubrication and grease thickener effects, etc.) are only briefly mentioned, as if familiar to the reader, but without providing any references for further reading. I feel this reduces the overall usefulness of the review to the general WES reader, and so encourage the authors to go back through the paper, adding pertinent references for all such concepts throughout. Remember, many readers will have non-tribological/non-bearing specific backgrounds. In order to maximise the value and impact of this review, such readers should be provided with clearly signposted references in

which they can learn more about these concepts. There are also a good few instances where claims/facts are stated without a suitable accompanying reference to back up that claim. Finally, I'd note that this review paper has a relatively low number of references utilised overall. While this may be appropriate in some cases, I believe this particular review would benefit from a broader representation of relevant literature (detailed in "Specific comments").

[More literature has been added](#)

6) The guidance provided on which methods to use and when is arguably fairly limited. For example, in one instance, a total of 8 different methods are indicated as being suitable in your flow diagram at one point, without any more specific guidance on which might be best (for instance, I don't think you explicitly state that approximate methods should be considered as less accurate etc.). Based on your familiarity with the various methods, the foundations of their development and extent of experimental validation (which I am aware is low in all/most cases), I wonder if the authors might be able to provide a clearer path to delineating and selecting an appropriate method. It may be this is simply not possible at this stage. However, if that's the case then perhaps the best advice is to stick as closely as possible to ISO method(s) and their extensions, including only the necessary add-ons for the case one is dealing with. The logic behind this would be that design certification often require some chain of evidence/justification, which would best be provided by links to an international standard – at least until some other method is clearly demonstrated to be superior. I am very happy to be told I am wrong about this, but either way I think a more detailed discussion of deciding which method(s) to use would be helpful.

[More guidance was added in Section 4.1, see also replies below in this document](#)

7) The paper feels like it's missing a section on "Current challenges and critical future work". This is a topic for which it feels like we are still at the beginning of its proper scientific exploration. This review should therefore provide a roadmap for overcoming current challenges and improving the rating life predictions for oscillating bearings in wind turbines. This becomes even more critical if, as discussed in point 6, we don't currently have any good way to decide between the various available methods in some instances. Can you outline the current knowledge gaps and indicate the necessary experiments, data, analyses and modelling work which would allow us to bridge them?

[Section "current challenges and future work" was added](#)

#### **Specific comments:**

Abstract: "calculation" used twice in first sentence. The abstract also feels vague, can your overall recommendations and findings be listed more explicitly? Similarly for the application to wind pitch and yaw bearings.

[The recommendations mostly refer to approaches that should be used under various circumstances; neither the approaches nor the circumstances can be briefly explained in the abstract. Main findings are difficult to note too. The abstract is brief because more detail is given in the paper itself.](#)

L11: "change the wind's angle of attack as it acts on the blade." Perhaps better as "the blade's angle of attack"?

[Changed as suggested](#)

L12 "Movements in modern turbines mostly consist of small oscillations with the occasional 90 degree movement to bring the turbine to a halt." -> "Pitch control actions in modern *wind* turbines mostly consist of small (x degs) oscillations with the occasional 90 degree movement to bring the turbine to a halt" (Language suggestion, plus, please indicate what "small" means here).

[Changed to:](#)

[Movements in modern wind turbines mostly consist of small \(typically < 10°, often as small as < 1°, cf. Stammler et al. \(2020\)\) oscillations with the occasional 90° movement to bring the turbine to a](#)

halt.

L13 “Similarly, yaw bearings rotate the turbine to face into the wind. Their movements are typically fewer and, depending on the site and the yaw system design, longer.” Please revise language, this is unclear and imprecise as written.

Changed to:

Similarly, yaw bearings rotate the turbine to face into the wind. Their movements are typically fewer and, depending on the site and the yaw system design, longer (< 10° during power production but potentially more while idling) while they do not tend to become as low (< 1°) as pitch angles (Wenske, 2022).

L15 “Rolling bearings under oscillatory movements are commonly associated with wear damage to the raceways and rolling bodies (Behnke and Schleich, 2022; Stammler, 2020; Grebe, 2017; FVA, 2022; de La Presilla et al., 2023)” -> Is damage more common in general, or is it that the damage that it does experience is wear more often than not? Please order references chronologically.

Wear can occur, there is no mention of how common it is (we are not aware of any such statistics). We are not sure if this answers your question, but the sentence has been rephrased to:

Rolling bearings under oscillatory movements are commonly associated with wear damage to the raceways and rolling bodies (Grebe, 2017; Stammler, 2020; Behnke and Schleich, 2022; FVA, 2022; de La Presilla et al., 2023). Wear can set in very quickly, but it can also be prevented by a number of measures (Schwack, 2020; Wandel et al., 2022).

References ordered chronologically.

L16 “In some cases, such as large amplitudes, varying amplitudes, or the use of oil lubrication, wear is unlikely to occur and rolling contact fatigue becomes more relevant.” -> Large amplitudes of what? (I assume motion, but you could mean load), please be more precise with language.

Changed to “large oscillation amplitudes”

L18 “and ensure they do not cause a failure of the bearing.” This sentence feels open ended and it’s not immediately clear what it adds.

Shortened to “Engineers should consider both types of damage as a possible failure mechanism.”

L19 You indicate that wear is maybe a dominant failures more, except under circumstances that don’t apply to pitch or yaw bearings (as far as I’m aware), but then say that this paper is going to review rolling contact fatigue... It feels as if like you start by outlining why a different paper is needed. Also, when describing wear vs rolling contact fatigue circumstances you don’t outline which yaw and pitch bearings may fail into and why. Please revise this discussion and provide further info on yaw and pitch specific failures.

Wear can occur in pitch and yaw bearings, (Bartschat, 2023) but how often it does is difficult to tell, there are no available statistics on this issue. It can also occur without causing failure but accelerate RCF.

Added information:

In many cases, such as large oscillation amplitudes, or the use of oil lubrication, wear is unlikely to occur and thus, rolling contact fatigue becomes a more important focus. Moreover, depending on its severity, wear in itself doesn’t necessarily cause a complete failure of the bearing but it can also accelerate rolling contact fatigue FVA (2022a, b). Engineers should therefore consider both wear and rolling contact fatigue as a possible failure mechanism.

L20 “There are a number of approaches for rolling contact fatigue life calculation in the literature,

see Sadeghi et al. (2009) and Tallian (1992) for an overview, but they are mostly intended for rotating applications.” I think there are other good references to include here, please consider whether those listed are sufficient (I am a big fan of Zaretsky 2016 - Rolling Bearing Life Prediction, Theory, and Application

<https://ntrs.nasa.gov/api/citations/20160013905/downloads/20160013905.pdf> )

The two listed reviews are very comprehensive (in the sense that they cover a lot of models) which is why they were chosen. The review by Zaretsky that you cite only covers three models, which are all closely related to the one used in ISO, and all of which are covered in Sadeghi (2009), while Sadeghi alone covers 18 probabilistic and 15 deterministic models, though more superficially than Zaretsky – but at this stage of the paper we think a broad but superficial overview is sufficient.

The given citation was however added to the introduction chapter because it includes a thorough overview of basic rolling contact fatigue related information.

Figure 2: I am struggling to interpret the left hand side of this figure, why does is the blue line continuously loading, whereas the red line has zero regions? Please provide a more detailed description to help the reader.

The absolute value of the angle in the left figure is relatively meaningless, the red movement oscillates around a 0° position but it might as well oscillate around any other position, likewise for the blue movement. Relative movement of the bearing is the driving factor in rolling contact fatigue as it causes load cycles in the raceway.

We tried to clarify this by modifying the test and adding a footnote:

Some of the ISO-related methods are intended for constant oscillation amplitudes as depicted red in Fig. 2, where an oscillation with a constant amplitude about a position of 0° is shown<sup>2</sup>, while some other ISO-related methods and all non-ISO related methods are intended for arbitrary movement as depicted blue in Fig. 2.

<sup>2</sup> Rolling contact fatigue is driven by relative movement of one of the rings to the other, which means that the mean position of the oscillations in Fig. 2 only moves the position where load cycles occur on the raceway but has no effect on the life of the bearing. The critical difference between the blue and red lines is their relative movement, not their absolute position.

Line 37: “Fundamentally, rolling contact fatigue in oscillating applications is caused by a rolling element repeatedly rolling over locations on a raceway, as is the case in rotating applications.” Maybe the reader could be given a little more lead-in to considering rolling contact fatigue. I suggest this as many engineers will be more familiar with cases of fatigue cracking and rainflow counting methods etc, rolling contact fatigue is quite different to that, since it is the passage of rollers which causes stress cycles and not simply the applied load varying. Some more discussion of this would, I feel, be helpful.

Added a paragraph on rolling contact fatigue in the Introduction:

Rolling contact fatigue is a possible failure mechanism of bearings. It is caused by the fact that, even under a constant external load, movement of the bearing (rotation or oscillation) causes movement of the rolling bodies (balls or rollers) relative to the bearing rings. If the rolling bodies transmit load to the raceway, their movement leads to stress cycles, because every location of the raceway changes from a loaded state while it is in contact with a rolling body to an unloaded one while it is not (cf. Fig. 6, left hand side, for a typical case in a rotating bearing). The resulting stress amplitudes can, over time, cause fatigue damage on the raceways, or, less frequently, the rolling bodies. The driving stress for rolling contact fatigue is typically considered to be shear stress. Fatigue can be initiated from shear stress below the surface of the raceway (subsurface fatigue) and from shear stress at its surface (surface fatigue) (Lundberg and Palmgren, 1947; Ioannides et al., 1999; Harris and Kotzalas, 2007; Zaretsky, 2013).

Equation 1 – please use the proportionality symbol here, as the tilde is ambiguous in its meaning.

All tilde occurrences in the paper have been changed to the proportionality symbol.

L44 I'd include a good background reference on this material, e.g. Zaretsky 2016 as above. Also, I'd suggest providing some discussion of the limitations of RCF modelling/prediction.

Added (Lundberg and Palmgren, 1947, 1952; Harris and Kotzalas, 2007; Zaretsky, 2013)

L46 I'd recommend defining this predicted life as the "rating life" to distinguish it from the observed/service life seen in the field.

Changed the sentence to:

They assumed the bearings to be rotating.  $L_{10,rev}$  then gives the number of millions of revolutions at which 10% of bearings are expected to suffer the first visible raceway damage, also called "basic rating life".

L54 "For small oscillation amplitudes,  $a_{osc}$  typically becomes very large" this sentence doesn't really add much as it is. Are you able to provide some ballpark of the size of  $a_{osc}$ ? E.g. "commonly falls in the range  $10^x - 10^y$ " or similar.

Changed the sentence to:

For small oscillation amplitudes,  $a_{osc}$  typically becomes very large, with  $a_{osc}$  commonly (but not always) being in the range of 1...1000.

L55 "There are two possible definitions of an oscillation "amplitude" " – technically there are an infinite number of ways one might define this amplitude, I'd change "two possible" to "two common"

Changed as suggested

L56 "For small oscillation amplitudes, much of the existing literature will predict a high likelihood of wear, particularly for grease-lubricated bearings (Behnke and Schleich, 2022; Stammeler, 2020; Grebe, 2017; FVA, 2022). Nonetheless, as discussed in Sec. 3 of this review, it is definitely possible for rolling contact fatigue to occur without wear<sup>2</sup> even for oscillating amplitudes as low as  $\theta = 1^\circ$  ( $\phi = 2^\circ$ )." I agree this is important context, but it feels a little shoe-horned in here. Is this the best place for this information, can you expand a little to give the reader a little more to grab hold of?

Incorporated this information into the introduction instead

Equation 3 – you use the notation  $a_{OSC}$  in Equation 2, but then switch to  $a_{Harris}$  for Equation 3. Please determine a way of making it clear to the reader that the latter is an instance of the former (it is reasonably clear that this is the case from context alone, but for the sake of rigour I'd like to see it made more explicit).

Added the sentence "All factors  $a$  in this paper are instances of  $a_{osc}$  as shown in Eq. 2."

Line 67 "Thus, taking an exemplary bearing that oscillates with an amplitude of  $\theta = 10^\circ$  and that, if it were rotating, would have a life of  $L_{10,rev} = 1$  million revolutions, and applying Eq. 2 and Eq. 3 gives a life of  $L_{10,osc} = 90^\circ 10^\circ L_{10,rev} = 9$  million oscillations according to the Harris factor. This is because it will execute an arc of  $A = 40^\circ$  per oscillation, which is considered as 1/9 th of a rotation by the Harris factor" While a worked example does help make things clear for the reader, I wonder whether readers will need such a simple equations explained in such detail?

It is a very simple example but understanding the Harris factor is the most essential lesson from this paper that anyone who works with oscillating bearings needs to take away. Therefore we would like to keep it.

Line 74 I think it's perhaps not an exact equivalence between Harris and LRD automatically, since Harris didn't deal directly with changing load conditions, while LRD does. Is it more correct to say LRD is equivalent to applying Harris independently to each different load case?

Yes, we extended the following sentence:

Doing so is in principle identical to using the Harris factor, if the Harris factor is used to sum up movement independently at each of the same load cases.

Line 78 Please indicate to the reader that these two effects will be described in detail below.

General comment – we are learning about what the loading etc looks like for an oscillating bearing by going through a series of incorrect or approximate approaches. This means the reader has to do a lot of mental gymnastics to keep track of what is actually happening versus what people assumed was a reasonable approximation. I think perhaps the paper would serve the reader better if early on there was a section which simply described the true characteristics of loading (along with any other pertinent effects) in oscillating bearings (as per Fig 5). When discussing the various approaches, the reader will therefore know the “ground truth” and hence be able to better follow where approximate methods miss important aspects of the real world case.

Additional section 1.1 has been added

L86 “but without a derivation of the approach” does “the approach” refer to the original or simplified one?

Changed to “but without a derivation of the simplified approach”

L86 Footnote 6 is rather long and difficult to follow since it seems to assumed familiarity with the works it mentions. Please consider rewriting for clarity and possibly moving this into the main paragraph, rather than as a footnote.

The footnote was intentionally not placed in the main paragraph because it is supposed to give background information for readers that want to look into the original references, but is not required to understand the main paragraph. Nonetheless we added information for clarification.:

Breslau and Schlecht (2020) give a more appropriate treatment of this effect by introducing the factor  $a_{osc,2}$  with their Eq. 19, which does not contain the simplifications taken by Rumbarger in his simplified approach. This equation was rearranged (without simplifications, but to obtain a less cluttered equation) by Houpert and Menck (2021) into a corrective factor called  $f\theta_{crit,i,o}$  in their Eq. 45, here used for the recommended approach.

L88 Is it necessary to list every combination of “a\_XXX” notation that has been used in the literature for the oscillation factor? We expect differences in notation and naming from paper to paper, but I'd expect readers to be able to cope with that by simply reading the work to find out what notation is being used. There are currently a great many footnotes dealing with notation and it feels unnecessary.

Hence why they were included as footnotes, some of the publications contain a number of factors and we wanted to be completely clear which factors are being referred to (because, as shown in this review, there tend to be quite a few misunderstandings in the world of oscillating bearings)

Fig 4 lacks units on the polar plot and is difficult to interpret, what am I looking at here? What does the radial scale mean? why do all fluctuations disappear for  $\theta = \theta_{crit}$ ?

Changed the figure to another one that is hopefully easier to interpret:

**Figure 4.** Rumbarger effect: stressed volume on the inner ring as a function of inner ring angle  $\theta$  relative to  $\theta_{crit} = \theta_{crit,i}$ , for  $\theta < \theta_{crit}$  and  $\theta > \theta_{crit}$ . Yellow volume is stressed twice per oscillation cycle (cf. Fig. 3), red volume is stressed four times per oscillation cycle. Black volume is never stressed. Only stress cycles for the inner ring are shown.

L 105 “The recommendation in Eq. 5” I’m not sure this makes sense, “the form of equation 5” maybe?

Changed as suggested

General comment – currently this reads as a long list of things people did, with continual caveats, corrections and footnotes. The paper would benefit from a careful consideration of structure and narrative in order to make this as easy to follow for the reader as possible. Perhaps a graphical description of early summary of all developed methods, how they relate to each other and where in the paper they will be discussed would help?

Only a few of the methods (Rumbarger’s approaches and Houpert’s, and the people applying them) really relate to each other, while a lot of the other publications effectively exist in a vacuum. A historical summary roughly reads like shown in the following. Please let us know if the paper would benefit from showing this in a graph:

Rumbarger and Jones(1968) introduced Rumbarger effect, was simplified (with error) in Rumbarger (2003), Harris et al. (2009)

Houpert (1999) introduced Houpert effect

Breslau and Schlecht (2020), Houpert and Menck (2021) corrected Houpert (1999) and introduced a simplified (but correct) version of Rumbarger and Jones (1968)

Schmelter (2011), Schwack et al. (2016) and Wöll et al. (2018) applied Harris et al. (2009), Houpert (1999).

Hwang (2023) and Münzing (2017) apply Harris et al. (2009)

Menck (2023) generalizes the approaches by Breslau and Schlecht (2020), Houpert and Menck (2021)

Hai and the other non-ISO related methods effectively exist outside the above literature independently for themselves.

L109 : “Strictly speaking, the life of an unevenly stressed volume (as illustrated 110 in Fig. 4, yellow and blue) is not the same as that of an evenly stressed volume which occurs in a rotating bearing (identical to Fig. 4, red)” Do you have a reference for this?

No, this is an original “finding” or note of this paper that is elaborated in Appendix C. It follows from Eq. 1, where the volume  $V$  has exponent 1 and the stress cycles  $N$  have exponent  $e$  ( $\neq 1$ ). There is not much more information in the paper because this effect is quite inconsequential. Added the following footnote (and additional text) for clarification:

Strictly speaking, the life of an unevenly stressed volume (as illustrated in Fig. 4, right hand side) is not the same as that of an evenly stressed volume which occurs in a rotating bearing<sup>16</sup> (identical to an oscillating bearing with  $\theta = \theta_{crit}$ ) if the total movement of both bearings is the same.

<sup>16</sup> This follows from Eq. 1, where the volume  $V$  has exponent 1 and the stress cycles  $N$  have exponent  $e \neq 1$ .

L112: "Recommendation" again, I don't feel this is the correct word here

Changed to "The factor chosen for Eq. 5 thus follows the above-mentioned publications."

L120 Footnote 14 is very dense and really gets down into the weeds, in particular it introduces contexts and notation (e.g. load integrals) which are not utilised or fully explained in this review. Either these more complex points are important enough to be included properly, or I'd recommend a briefer footnote which simply gives the reader appropriate context and the main outcomes.

This footnote is intended for readers who want to look deeper into the derivations, and it is intended to point out that the approaches by Houpert and Menck (2021) and Breslau and Schlecht (2020) are very similar but not perfectly identical. This was clarified with a sentence in the beginning:

<sup>17</sup> The two approaches are not completely identical but very similar: [...]

L128 It's been mentioned a few times by now, but I am still unsure specifically what the "Houpert effect" is describing in any sort of detail. Maybe link the name to Figure 5 behaviour more explicitly?

Changed by adding a sentence:

Aside from the effects also considered by Harris, the Houpert effect considers that the stress cycle history of the moving ring will be different for an oscillating bearing than for a rotating one. This is illustrated in Fig. 5 for an exemplary element on the moving ring.

L133 "For very small oscillations  $\theta \rightarrow 0^\circ$  ( $\phi \rightarrow 0^\circ$ ) on the other hand, the elements increasingly converge toward the stress cycle history seen in a stationary ring, see Fig. 5" It seems that you're possibly saying that it will converge to the stress cycle history of a stationary ring in a rotating bearing (which I don't think it does), so instead I guess you mean that for small cycles the stress time history for the moving ring in an oscillating bearing becomes similar to the stress cycles for the stationary ring in that same oscillating bearing? Either way I think some clarification is needed here.

This is somewhat complicated to express in words but in Houpert's derivations it indeed converges against the stress cycle history of a stationary ring in a rotating bearing, because Houpert's effect alone (unlike Rumbarger's) does not consider the fact that there is a discrete number of rolling elements in the bearing; rather, he integrates over the circumference of the bearing and implicitly assumes all locations to experience the same number of stress cycles. (This is a standard procedure for the life calculation of rotating rolling bearings, ISO 281 equations are all based on this same way of modeling stress cycle history)

This was clarified by means of yet another footnote:

<sup>20</sup> In Houpert's model the stress cycle history of an oscillating ring converges, for small oscillations, against that of a stationary ring in both a rotating and oscillating bearing. These two cases (a stationary ring in a rotating and oscillating bearing) can be considered identical here because Houpert's effect alone, unlike Rumbarger's, does not consider that there are a discrete number of rolling elements in the bearing for the circumferential distribution of load cycles. Rather, he assumes all circumferential locations to experience the same number of stress cycles (with differences in load cycle magnitude only), as is common in a rotating bearing, and integrates over a continuous load distribution around the circumference. This is standard practice for the life calculation of typical rotating bearings and as such also employed in ISO 281.

Equation 6 how does a\_Harris change between stationary and rotating rings? I don't see what's different in the mentioned cases shown in this split equation.

$a_{\text{Harris}}$  does not change, but the Houpert factor converges against the life of a bearing with both rings assumed stationary relative to the load, to which  $a_{\text{Harris}}$  is applied. Changed the text as follows:

$a_{\text{Harris}}$  in a bearing with both rings for  $\theta \rightarrow 0$  stationary relative to load<sup>21</sup>

<sup>21</sup> Both rings being stationary relative to load slightly reduces the life as compared to standard calculations (in which one ring is assumed to be rotating) because it increases the equivalent load of the ring which would otherwise be assumed to rotate. It does not affect the factor  $a_{\text{Harris}}$ .

L138 “If applied correctly, the Houpert factor will either be identical to  $a_{\text{Harris}}$  in the above given cases or shorten the life of the bearing in all other cases. The Houpert effect is thus most noticeable for narrow load zones and small oscillation angles.” I don’t see why the latter follows the former (as implied by the use of “thus”), perhaps this is additional information rather than being implied by the first sentence?

“Thus” was meant to refer to Equation 6 and the information before the sentence “If applied correctly”. Removed the “thus” and added symbols:

The Houpert effect is most noticeable for narrow load zones (small  $\epsilon$ ) and small oscillation angles  $\theta$ .

Footnote 18: Again there is lots of additional info being given about notation used in other work, I am just not sure if that is really adding anything or simply risking confusing the reader. Please consider.

The information may be confusing but it is close to impossible that anyone understands these minute details if they are not mentioned here, and for readers who wish to employ the Houpert factor alone, this is necessary information.

L149 “The above three factors have been covered in a number of publications” please provide a more complete list of these references here, even if you do go on to then point to the most recent.

Included a footnote:

<sup>24</sup> A comprehensive list including all publications with relation to the factors, to the best knowledge of the authors, includes: The factors are derived in Rumbarger and Jones (1968); Houpert (1999); Rumbarger (2003); Harris et al. (2009); Breslau and Schlecht (2020); Houpert and Menck (2021), and they are used or discussed in some form in Schmelter (2011); Schwack et al. (2016); Münzing (2017); Wöll et al. (2018); FVA (2021); Menck (2023); Hwang (2023)

L164 Why are the various methods below this point introduced in reverse chronological order? Surely you should start with Hai et al. (2012) and work your way forwards in time to Menck (2023).

The review points out differences of Hai et al and Wöll et al to Menck, and hence it is necessary to start with Menck so it can be referenced in the text that follows. The approach by Hai does not build on the other publications, and the other publications do not build on it either, so the order of appearance can be chosen arbitrarily.

Kept Menck (2023) as the first reference but reordered the others.

L165 “whole bearing” does this mean that Menck (2023) calculates life for individual raceways and then combines these into a total bearing life afterwards? If so I’d suggest making that clearer in the description of Menck (2023) in the previous paragraph.

Yes, however the critical point here is that Menck (2023) starts with segments of a raceway which are even smaller than an entire raceway

Changed a sentence in the description of Menck to:

The individual survival probabilities of all segments can then be combined into raceway lives, which can be combined into a total bearing life.

Footnote 21 appears to contradict a sentence which follows, which seems to indicate equivalence only in cases of sinusoidal movements.

The following sentence points out they (Wöll et al) showed equivalence only for sinusoidal movements, but the footnote points out equivalence in all cases, because of the review author's understanding of the model

Changed the footnote and moved it to the end of the second sentence:

[...] The model is shown to be identical to a bin count using the Harris factor, cf. Sec. 2.1.1, for simple sinusoidal movements<sup>27</sup>.

<sup>27</sup> Even though they only show equivalence for sinusoidal movements, one can conclude that their numerical approach is equivalent to usage of the Harris factor for any type of movement if one evaluates the life and the corresponding movement of the bearing as shown in Sec. 2.1.6 with each time step used as a bin, and uses only the Harris factor.

L167 "For a stochastic time series, their numerical approach produces a shorter life than either Harris', Rumbarger's, or Houpert's approaches applied to a bin count." Where is this shorter life shown, can you add a reference or other evidence to demonstrate this?

Table 4 in Wöll et al (2018) and the sentence that follows ("Evidently, the numerical approach yields the highest failure probability and thus the lowest lifetime")

L173 "and conclude that using these bin counts "overestimates the lifetime for non-sinusoidal loads and speeds"" can you please comment on whether this conclusion is correct or not (I assume not as you indicate they use some erroneous formulations but this isn't made explicit either way).

It's difficult to comment which of these methods is more accurate because they all contain simplifications; their conclusion is obviously correct if their numerical model is used as a reference but there is no reason why it should be considered as more accurate than the other methods.

Added a sentence:

It is not possible to assess the accuracy of this statement because their model is based on the life of the whole bearing and thus also includes simplifications as pointed out by Sec. 2.2 of Menck (2023).

Also intensified the wording in Hai et al from "The simplifications make it difficult to establish" to "The simplifications make it impossible to establish"

L173 "They also produce a simple method to calculate an equivalent load for oscillating loads but it fails to take local effects into account as accurately as Menck (2023)." Can you please indicate where this is demonstrated (in Menck (2023) perhaps?).

Menck (2023) Sec. 2.2

L190 Typo "made make"

This was supposed to read as (The simplifications made) (make it difficult [...]) but we removed the "made" now

Section 2.1.5: As mention previously, I feel there needs to be an earlier section describing all relevant real world effects in oscillating bearings, rather than encountering these various concepts one at a time and dispersed throughout discussions of simplified modelling/analysis approaches.

Added section 1.1 – Operational conditions for oscillating bearings

L195 "the orthogonal shear stress below the surface changes from maximum ( $+\tau_0$ ) to minimum ( $-\tau_0$ )" There is quite a lot of complexity surrounding these stress components and how they behave,

therefore please link to a reference which provides detailed information, e.g. A Review of Rolling Contact Fatigue by Sadeghi et al. 2009 (or similar).

Added (Lundberg and Palmgren, 1947; Harris and Kotzalas, 2007) because they both include the derivation for the standard  $\tau_0$  value

L196 "This load cycle does not take place to the full extent at the outer ends of an oscillation cycle as depicted in Fig. 3." I don't think Fig 3 is explicitly showing this, it is maybe something which may be "inferred from" Fig 3, or is a result of the behaviour therein?

This was meant to read as "This load cycle does not take place to the full extent at the outer ends of (an oscillation cycle as depicted in Fig. 3)".

Reading this now we agree this is confusing wording. Moreover, the information is already included in the following sentence when the central image of Fig. 6, blue case, is being referred to. Therefore changed to:

This stress cycle history behaves different in oscillating bearings: [...]

L201 "None of these effects is considered in the ISO-based approaches named herein." To help the reader, can you provide a little more to remind them which of the described approaches fall in this category (e.g. "this being all approaches outlined in Sec X.Y").

Changed sentence to:

None of these effects is considered in the ISO-based approaches (all approaches covered in Sec. 2.1) named herein.

L205 "As far as the authors are aware, there are no simple models to estimate the thickness of the lubrication film as a function of the oscillation and thus determine its potential effects on rolling contact fatigue" You mention that poor lubrication might lead to wear (which is not fatigue), but then indicate that we are currently unable to determine the effect of lubrication on fatigue. Do you perhaps need to include an earlier sentence which indicates that as well as wear damage, lubrication also impacts rolling contact fatigue (although I appreciate that the lines can become fuzzy here, since surface initiated rolling contact fatigue can be argued to include some elements of wear...). Anyway, as written it feels a little confusing for the reader, so please consider a suitable revision in one form or another.

Added an introductory sentence:

Lubricant film quality is well known to have a significant impact on rolling contact fatigue life (Ioannides et al. (1999); and Kotzalas (2007)). The thickness of the lubricant film is affected by oscillation, [...]

General comment: Throughout the paper, many complex concepts (e.g. subsurface stress time histories in rolling contact, lubrication and grease thickener effects, etc.) are briefly mentioned as if familiar to the reader, but without providing any references for further reading. I feel that this reduces the overall usefulness of the review to the general reader, and so encourage the authors to go back through and add in pertinent references for all such concepts throughout. Remember, many readers will have non-tribological/non-bearing specific backgrounds. In order to maximise the value and impact of this review, such readers should be provided with clearly signposted resources to learn more about concepts that may be important for them to consider within their wind-energy-meets-oscillating-bearings research.

Added more context:

As far as the authors are aware, there are no simple models to estimate the thickness of the lubrication film as a function of the oscillation and thus determine its potential effects on rolling contact fatigue. Most bearings are grease-lubricated (Lugt, 2009), including most pitch and yaw

bearings (Becker, 2011; Wenske, 2022). Grease consists of, among other things, thickener and base oil (Lugt, 2009). Film thickness estimation would likely become even more challenging with grease lubrication due to the effect of the thickener.

L207 “Therefore, the effect of lubrication is mostly ignored in all models of which the authors are aware.” ISO 281/16281 include some effects of lubrication in the modified life factors. I am aware this in no way accounts for oscillating behaviour, but since some accounting for lubrication is present I would ask the authors to be a little clearer in what is included and what is not. E.g. maybe rephrase to something like “Oscillatory effects on lubrication are mostly ignored...”

The sentence was supposed to only refer to models for fatigue life in oscillating bearings. Added context:

[...] mostly ignored in all models for rolling contact fatigue calculation in oscillating bearings [...]

2.1.6 Binning: You have already talked about binning in some other contexts above, there is risk of equivocation of those various concepts and so I’d suggest a more descriptive title for this subsection.

We don’t understand this point, this subsection talks about binning and the previous discussions did, too. Nonetheless, changed the title to “Binning for oscillating bearings”.

L211 “The most accurate way to calculate the rolling contact fatigue life... according to the assumptions in Eq. 1 made by ISO related approaches... is to use the Finite Segment Method according to Menck (2023)” This is a fairly strong claim that is being made. Based on what I know of these methods I absolutely concede this is likely to be the case, but has that been demonstrated explicitly anywhere? To fully back up this claim, one would need to have experimental verification I’d think. Perhaps maybe a more qualified statement, such as “It is argued that the most accurate way to calculate... is likely to be the Finite Segment Method according to Menck (2023), because...”

The claim argues that Menck (2023) is most accurate according to the assumptions of Eq. 1, not necessarily in relation to test results. I.e. Menck (2023) is the most accurate method if one sets out to accurately apply Eq. 1 to an oscillating bearing. Therefore it is sufficient to have a theoretical argument that proves this claim. That argument can be found in Menck (2023), Sec. 2. Therefore changed to:

As argued in Sec. 2 of Menck (2023), the most accurate way to calculate the rolling contact fatigue life of a bearing under varying operating conditions according to the assumptions in Eq. 1 made by ISO-related approaches is to use the Finite Segment Method according to Menck (2023). This is because the Finite Segment Method considers local load changes rather than summing global, location-independent bearing damage over time.

L216 “Doing so for oscillating bearings necessitates the use of bins” This statement is ambiguous, bins of what? Please revise for clarity and specificity.

Changed phrasing to:

“Doing so for oscillating bearings necessitates the use of bins representing similar operating conditions in combination with oscillation factors.”

L220 “along with a number of other assumptions made by Lundberg and Palmgren (1947)”. Please provide references to more recent works which critique rolling contact fatigue formulations/assumptions (e.g. that of Erv Zaretsky, listed previously). This will provide readers with a more up to date critical analysis.

All the oscillation factors are essentially based on Lundberg and Palmgren (1947) though, so they contain the same simplifications, hence the citation. Furthermore, the argument here is supposed to state that they are an approximation as compared to the correct application of Lundberg-Palmgren Theory to an oscillating bearing, not compared to experimental results. (though a proper

theoretical application of LP-Theory should obviously result in a better experimental result, logically, this claim is not being made here).

It is an approximation since the aforementioned factors have all been developed for constant oscillation amplitudes around the same mean position and they all assume there is a constant load acting on the bearing as it moves, along with a number of other assumptions made by Lundberg and Palmgren (1947), resulting in the life of a whole bearing, a process in which local information is lost.

L222 “Typically, variable load is taken into account in fatigue calculations by using rainflow counting” This is true for classical fatigue of structural components (e.g. beams etc.), but is not used for rolling contact fatigue. Since we have been discussing the latter, there is a risk here that the reader assumes rainflow counting is applied for rolling contact fatigue analysis also. Please provide further clarification here to avoid such confusion.

Changed sentence to:

Typically, variable load is taken into account in fatigue calculations by using rainflow counting (ASTM, 2017) for classical fatigue of structural components.

Equation 7: The notation here is not properly defined, e.g. please be explicit about what  $N_i$ ,  $P_i$  and  $P_m$  denote – and please include this immediately following the equation itself.

Clarified

L231 References not provided in chronological order.

ordered

Footnote 30 and Lines 235-238: These both constitute information of additional approximations that either do or may form part of the analysis currently being described. However, there is no further context provided by the reader of the quality of approximation that either may represent. If further information on this (e.g. from analyses in the literature) may be given then please include it. At the very least, please point out that these additional approximations are increasing the uncertainty surrounding the rating life values we obtain (which themselves contain uncertainty as ISO fatigue equations are imperfect to begin with). This is fine, but I feel the reader should be made aware that these additional approximation come at a “cost”.

Changed footnote:

<sup>36</sup> Strictly speaking, this equation only applies for a constant load direction, but it can be used as an approximation with some variations in the load direction, too, as proposed here. The same applies for Eq. 8. This increases the uncertainty surrounding the calculation result somewhat, which is explored in Sec. 4.4.

General comment: There are a lot of approximations and uncertainties being stacked on top of one another in these various methodologies. Given there is also a lack of experimental data to indicate how accurate any of these methods are, surely this provides at least one aspect of “critical future work” which should be highlighted?

Sec. 4.4 indicates, though, that there is not a huge difference between either of the methods; experimental deviations to any model are likely to be greater than differences in between the various models. Moreover, application of the Palmgren-Miner rule is common practice in industry (not just in wind energy but everywhere)

While validation is never a bad thing one must take into account that financial means for the limitation are always limited and may be better suited in areas where bigger question marks pop up.

L239 Notation in equations, again not defined or explained well.

Changed to

If it is not possible to determine  $P_i$  for each time step, potentially due to the calculation being too costly, it is possible to apply Eq. 7 to the force and moment components making up  $P$  (including radial force  $F_r$ , axial force  $F_a$ , and bending moment  $M$ ) and to then determine  $P_m = f(F_{r,m}, F_{a,m}, M_m)$  from a suitable function<sup>37</sup>  $f()$  based on their values  $F_{r,m}, F_{a,m}, M_m$  for each bin (calculated as per Eq. 7, but using  $F_r, F_a, M$  instead of  $P$ ).

<sup>37</sup> Functions  $f()$  for bearings with only radial and axial load components can be found in ISO 281 (ISO, d). Examples of a function  $f()$  for pitch bearings can be found in (Harris et al., 2009; Menck, 2020), where the latter publication is to be preferred.

Equation 8: Please provide one or more references for this equation. As previously mentioned, important background material is not being signposted for readers. Also subscript B missing on denominator  $\phi$ .

Corrected subscript and added reference to (cf. also Zaretsky (1997); Kenworthy et al. (2023))

Equation 8: I think this may be in an unhelpful form... As written the  $\phi$  have the same units as the life values. Hence, the total life of the bearing across all operating conditions (combined) is  $\phi_1 + \phi_2 + \dots + \phi_B$ . This means you actually have to know the complete life of the bearing to form that expression. But, if you multiply the top and bottom of the equation by  $1/(\phi_1 + \phi_2 + \dots + \phi_B)$  you end up with a form in which you only need the proportion of time spent in each operating condition. Note – using the form you wrote out for a finite set of load cases, and where each  $\phi$  is just the time spent in each, is essentially equivalent to the proportional approach I outline, but you have to make the implicit assumption that those load cases are proportionately representative of the lifetime conditions. Hence, I feel it better to explicitly include the concept of proportional time for the sake of clarity.

Changed to:

All of the bins  $b = 1 \dots B$  obtained are then typically combined into one final life using the Palmgren-Miner hypothesis (cf. also Zaretsky (1997); Kenworthy et al. (2023)) according to

$$L = \frac{1}{\frac{\phi_1}{L_1} + \frac{\phi_2}{L_2} + \dots + \frac{\phi_B}{L_B}}, \quad (8)$$

where  $L_1, \dots, L_B$  denote the life in bin  $b$ . This may be either the life in oscillations, revolutions, or time. Typically, the life would be in oscillations if oscillation factors have been used but it may be converted to time or revolutions.  $L$  denotes the total, combined life of all operating conditions. The variable  $\phi$  gives the proportion of oscillations, revolutions, or time performed in that bin. It is calculated according to

$$\phi_b = \frac{s_b}{s_1 + s_2 + \dots + s_B} \quad (9)$$

where variables  $s_1, s_2, \dots, s_b, \dots, s_B$  are the oscillations, time, or revolutions that occurred while in that bin, but must have the same unit as the lives in Eq.8. It follows that  $\phi_1 + \phi_2 + \dots + \phi_B = 1$ .

L252 “the most accurate approach ... is to use each single step... In order to account for oscillation effects, it would then be required to consider the larger oscillation cycle (amplitude) that a specific step is part of and adjust its life based on that, where the step will typically make up a fraction of the complete oscillation”. As per a previous comment, I’d again suggest a more qualified statement regarding what may or may not be the most accurate approach. Here I say this because you go on to outline how an additional approximation/interpretation of the data becomes necessary to implement in this way. Perhaps you mean accurate in terms of what we’re allowed to do under linear damage accumulation, in which case it may be possible to make a stronger claim. But, I wonder whether overlaying rainflow counted oscillations on top of varying loads moves us outside of where we’re strictly applying the linear damage rule as used by Palmgren-Miner? I am happy to take your lead on this, please just consider these points.

We would argue that the entire process of binning, strictly speaking, moves us out of a proper application of the Palmgren-Miner rule, cf. Sec. 2 of Menck (2023). But here the application of the Palmgren-Miner rule to a whole bearing is used as a reference, from which we attempt to deviate as little as possible. Changed text to:

It is worth noting that binning is solely used to reduce the number of data points from real-life data or a simulation. Using modern computers, if there is no hardware-specific necessity to reduce the number of data points, it is possible to use each single step taken from e.g., an aeroelastic wind turbine simulation or some other data set and treat it as a separate bin to which Eq. 8 is directly applied, rather than processing the steps into a reduced number of bins. From the perspective of a proper application of the Palmgren-Miner rule to a whole bearing, usage of each single step is the most accurate approach. It is thus both easier and less error-prone, as well as more accurate than binning beforehand

2.2 Non-ISO related approaches: The summary of existing literature/approaches is not in chronological order. Please start with oldest and work to newest unless there is a good reason for deviating from this.

Changed order

L260 “Individual loads are combined using the Palmgren-Miner hypothesis” Has the linear damage accumulation assumption (does it count as a hypothesis?) been explicitly introduced (in detail) somewhere in the paper, and linked to relevant references in the literature for the reader to learn more if necessary?

Yes, in Eq. 8, now with references

L262 “fatigue criteria such as Fatemi–Socie or Dang Van could also be applied” is it helpful to name these if they are not expanded upon? Maybe just say that they point out other criteria could also be applied. If you want to name them then please at least include a relevant reference for each.

Both of these criteria are sometimes used in other models so the fact that these specifically where mentioned may be interesting to some readers. Added references

L262 “They obtain empirical values used for the Palmgren-Miner hypothesis” empirical values of what?

Changed to: They obtain empirical values of the cycles to failure used for the Palmgren-Miner hypothesis from a test of a full-sized blade bearing

L264 “and further note that “a large number of tests are necessary for reliable results”.” Had they conducted such tests in their own work? Can you please comment in the paper as to whether they provide evidence that their approach works or is better/worse than others.

No, changed text to

However, they note that “fatigue criteria such as Fatemi–Socie (Fatemi and Socie, 1989) or Dang Van (Dang Van et al., 1989) could also be applied” in subsequent work. They obtain empirical values of the cycles to failure used for the Palmgren-Miner hypothesis from a test of a full-sized blade bearing and an assumed slope of the S-N curve from the literature. Further, they note that “a large number of tests are necessary for reliable results”, but that “currently, not enough tests have been carried out to determine a reliable service life” with their model.

L272 “They use orthogonal shear stress” the max value at each point in time?

Since they have a three-dimensionally discretized model (as stated in the text) there is no need to use the maximum value, they can use the actual orthogonal shear stress of each element over time and apply a rainflow count

L276 “the Weibull weakest link principle” Please describe and provide reference to relevant

literature (possibly Zaretsky 2016 again, he calls it strict-series-reliability).

Added a reference to Weibull (1939) though Escalero just calls it the “weakest link principle”

L276 “The authors demonstrate their method for a reference case in which a blade bearing was tested.” What was the outcome of this test/comparison? Did it provide a good prediction of observed life?

See Sec. 3, added reference to Sec. 3

L285 “The model is applied to rotating and oscillating bearings under constant operating conditions” Does this application imply anything regarding the efficacy of this approach? Please add some further comment or information.

We do not understand this question, how would this sentence imply anything beyond what it states?

L304 “none of the bearings show evidence of fretting corrosion” until now we have only seen mention of fatigue and wear damage. Why is this new type being included now, should it not appear earlier as well in that case? (I’d suggest including it in my suggested new section of real world information for oscillating bearings).

Fretting corrosion is a type of wear damage. Rephrased:

Despite the tests going as low as an amplitude of  $\theta = 1^\circ$  ( $\phi = 2^\circ$ ), none of the bearings show evidence of wear [...]

Footnote 32: You don’t say what x or b are in this note. We are also focussing on fatigue and not wear, hence this parameter has not previously been discussed and is arguably not helpful to readers not familiar with wear testing for oscillating bearings. I think this note can therefore be safely dropped. If it is to be retained then it should relate to material on wear introduced earlier so the reader can interpret the information in a useful way.

Added sentence:

Low values of  $x/2b$  are often used to indicate wear potential (de La Presilla et al., 2023).

L311 “The test duration is equivalent to the L10 of the ball screws“ is this the L10 for rotation or under oscillatory conditions?

It appears to be for a slightly modified version of the Rumbarger factor according to our best understanding. Changed text as follows:

The test duration is equivalent to the L10 of the ball screws, which Muenzing determines based on the simplified version of the Rumbarger factor found in NREL DG03 (Harris et al., 2009), cf. Sec. 2.1.2, which he modifies<sup>40</sup> to be equal to 1 for  $\theta \geq 90^\circ$  ( $\phi \geq 180^\circ$ ).

<sup>40</sup> The application of the Rumbarger factor in the reference takes place by changing the equivalent load P as done in other references (cf. Sec. 2.1.2) but his application, including his changes, are equivalent to those described here. The modification to  $a_{\text{Rumbarger}} = 1$  for large amplitudes is presumably the result of a misunderstanding: Münzing claims the NREL DG03 to state that for oscillation amplitudes of  $\theta > 90^\circ$  ( $\phi > 180^\circ$ ), the influence of the oscillatory movement can be neglected and the life of a continually rotating bearing can be used for an oscillating one. This is not stated in NREL DG03 though, rather, it implies that the life of a rotating bearing and that of an oscillating one are identical in the case of  $\theta = 90^\circ$  ( $\phi = 180^\circ$ ) only, but not for amplitudes exceeding this value (cf. Harris et al. (2009): “The total stressed volume and number of stress repetitions per cycle are identical to a bearing in continuous rotation when  $[\phi] = 180^\circ$ ”)

General comment: Combining the discussions of deviations between oscillating and rotating

bearings with experimental findings; it seems there is a natural expectations that oscillatory (fatigue) lives are longer than the equivalent rotating life (although wear is another animal!). If this is a reasonable inference then could/should this be given as an explicit interpretation? Section 3 currently lacks any concluding discussion which seeks to identify commonalities between experimental findings, if present.

It's reasonable to expect that the life of an oscillating bearing (measured in oscillations) is larger than that of a rotating one (measured in rotations); as stated in Sec. 2.1,  $a_{osc}$  is commonly in the range of 1...1000. We do not quite understand why you believe this follows from Section 3 though. There is no concluding discussion on commonalities because, frankly, most of the test results contain such a low number of tests that they are very difficult to interpret and there are not many commonalities between the few presented tests.

L330 "For the ISO-related approaches, recommendations are given according to the underlying physical phenomena considered in the derivations as described in this paper" So there is therefore an assumption applied that a method which explicitly includes a given phenomena is necessarily superior to one which doesn't. This is a reasonable basis on which to make these recommendations, but it could also be the case that (for various reasons) a simpler method is superior to a more complex method, even if the latter includes more effects. For instance, this could occur if more complex interactions are present which perhaps counteract impacts from the physical phenomena which the more sophisticated methods attempts to capture. As a result, it is perhaps worth highlighting at this point that recommendations based on included physical effects alone is the best we can do at present, but not guaranteed to produce better results in all cases.

It is indeed possible that a simple model is more accurate or that a randomly generated function produces even more accurate results, but that would be completely accidental, so we don't think it needs to be highlighted here. There is a chapter on test results which shows that there are only few published experimental results and that the experimental basis for any recommendation is somewhat shaky.

Footnote 33: please include relevant reference(s)

For the equation? The equation is the result of a back-of-the-envelope calculation, so there is no source, Harris (2007) and other publications contain similar equations, Menck (2023) also contains it but also without derivation; we could add a derivation but are unsure if this is useful

L341 "For the Rumbarger effect, based on Sec. 2.1.2 and App. A, the flowchart recommends combining this effect with the Houpert effect for non-axial loads (i.e., radial and moment loads)." The flowchart actually indicates this for non purely-axial loads (different to non-axial). The diagram is also a little confusing, since "yes/no" can be followed in two directions in many places, with no indication given as to which is preferential. Note for the legend entry with bold outline "for time series" isn't super clear. I initially looked for fully white boxes and saw none, only after this did I realise it was referring to the bold outline. I'd suggest a clearer indicator (e.g. dashed green bold outline instead?).

Changed to "non purely-axial"

Changed outline of boxes to magenta color

Section 4.1 (General comment): There is fairly limited guidance on which methods to use provided here. For example, at the first stage-gate whether the answer is yes or no a total of 8 different methods are indicated, without any further guidance on which might be best. Based on familiarity with the various methods, the foundations of their development and extent of experimental validation (which I am aware is low in all/most cases) I'd hope the author's might be able to provide a clearer path to delineating and selecting an appropriate method. It may be this is simply not possible at this stage. However, if that's the case then perhaps the best advice is to stick as closely as possible to the ISO method (so favouring ISO-based methods), including only the necessary add-ons

for the case one is dealing with. The logic behind this would be that design certification often require some chain of evidence/justification, which would best be provided by links to an international standard – at least until some other method is clearly demonstrated to be superior. I am very happy to be told I am wrong about this, but either way I think a more detailed discussion of deciding which method(s) to use would be useful.

We agree, added paragraph:

For general users seeking to apply a life calculation, ISO related approaches are preferred to non-ISO related ones due to their simplicity and the fact that there is much more empirical basis underlying them. In case of an invariant load direction and oscillation amplitude  $\theta$ , various methods are shown in the figure. Among the ISO related ones, that by Menck can be considered to be most accurate, however, it is also complicated to apply. A less accurate (i.e., an approximated) but simpler method will be most useful for most readers. Among the approximated ISO related methods for an invariant load direction and  $\theta$ , “Bins with Palmgren-Miner” is the recommended approach due to its wide use in many areas. Among the non-ISO related methods, Table 2 gives an overview of advantages and disadvantages of each method. Since only users with very specific aims will refer to these methods, it is up to readers to take their own decision as to which of these methods, if any, to use.

L365 “An exemplary cardan joint connects two shafts whose axes are inclined to each other” A simple diagram would be helpful here.

The introductory text really just adds some spice for the reader but is otherwise irrelevant to the calculation, hence, we think this is not necessary here.

L370 “According to Fig. 7” I think this would read better as “In the context of Fig. 7” At present it seems to imply that the time invariance is because of Fig. 7.

Changed as suggested

4.2 and 4.3 Applications: These are both very simplistic examples which basically demonstrate how to follow a flow diagram. Would it not be possible to go on to apply realistic loads for those components and example bearings in order to obtain life values, perhaps also comparing to what you’d get if a simpler formulation had been used instead of the recommended one?

A life calculation would not add a lot in our opinion, but the factors were now explicitly calculated and compared to each other for both cases. See updated manuscript.

L387 References given in reverse chronological order, please switch to chronological.

Changed order

L390 “Moreover, according to Sec. 3, the experimental validation for these models is still lacking. Therefore this section will focus on ISO-based approaches, which remain the most common life calculation methods for rolling contact fatigue.” Here you seem to apply some of the logic I suggested including in your recommendations for which methods to use, so it seems we are somewhat in agreement in the underpinning logic at least.

Yes

L393 “Moreover, the load direction changes slightly, though mostly for smaller loads (Menck et al., 2020)” Can you please expand on this for clarity. Surely the gravitational loads are constantly cycling and hence driving large load direction changes a lot of the time? (Is this perhaps overcome by one of the other load components?). I’d also suggest including a fuller description of the load conditions of pitch and yaw bearings in my suggested expanded Background section on slewing bearings in wind turbines.

The main load component that drives the loading within the bearing is the bending moment  $M$ , which

consists of two components,  $M_x$  and  $M_y$ .  $M_x$  is driven by gravitational loads but  $M_y$  at its peak load is bigger and therefore the resulting moment tends to be concentrated in the direction caused by  $M_y$  for high resulting moments. This can be seen in (Menck et al. 2020) Fig. 5: For high resulting moments  $M$  the load is more concentrated than for lower ones. And high bending moments are the ones that are driving the life (since  $P \sim M$ , approximately, and thus  $L \sim 1/M^3$ ).

Changed to:

“Moreover, the load direction changes due to the  $M_x$  component of the bending moment caused by gravitational loads, though for bigger resulting moments,  $M_y$  is driving the direction of the resulting moment (Menck et al., 2020).”

L394 “Therefore, according to Fig. 7, the Finite Segment Method (Menck, 2023) would be the most appropriate ISO-based method for an engineer to use” This is not a given from Fig 7 alone. Yes the figure indicates the other ISO-based methods are approximate, but the figure and accompanying text never make the claim that approximate methods are necessarily poorer than the rest. If such guidance is being given, please include this in Section 4.1 more clearly.

Changed sentence in 4.1: “Dashed arrows represent mathematical approximations, which are considered less accurate than exact calculations.”

L405 “is large enough to have rolling elements cover the entirety of the raceway at one point or another” reference?

Added a footnote with explanation:

<sup>46</sup>The entirety of the raceway is covered by rolling elements if for the largest amplitude  $\theta_{max}$  done by the bearing,  $\theta_{max} \geq \theta_{crit}$  is true. Since all pitch bearings perform  $90^\circ$  movements (Burton et al., 2011) (corresponding to  $\theta = 45^\circ$ ), this is achieved in virtually all pitch bearings: Due to the rolling element diameter being small compared to the pitch diameter (Wenske, 2022), pitch bearings commonly have close to  $Z = 100$  and more rolling elements and small values of  $\gamma$ . This means that for a four-point bearing as used in Menck et al. (2020),  $\theta_{crit,i} = 2.48^\circ$  and  $\theta_{crit,o} = 2.42^\circ$ , values which are easily exceeded by a pitch controller even without taking the  $90^\circ$  movement into account (Bossanyi et al., 2013; Bartschat et al., 2023).

L414 “The five approaches are ordered with increasing accuracy to the right of the figure” Accuracy implies “more correct with respect to the ground truth”, here I believe you are instead claiming accuracy under the assumption that linear damage accumulation is a reasonable approximation, please clarify this in the paper. Similarly for “This is the most accurate method and can be used as a reference for the others.”

Changed sentence to:

The five approaches are ordered with increasing accuracy to the right of the figure, where “increasing accuracy” means that the Palmgren-Miner hypothesis is applied as accurately as possible.

Footnote 40: References?

Added references (Lundberg and Palmgren, 1947; Harris and Kotzalas, 2007; ISO, a)

Figure 8: Why not have L10 in years, that’s much more meaningful to wind engineers. Similarly, results indicate rating lives of around 100 days or less, is this realistic? Please discuss.

Lives are given in h because, as you stated, they would be very low if shown in years. A discussion of the accuracy of calculated rating lives for pitch bearings is outside of the scope of this review and can be found in, for example, (Menck,2020)

L445 “The design of yaw bearings thus lends itself to binning, since detailed time series will typically

not be available” This is due to a lack of information, rather than this necessarily being a route to accurate design lives. I’d suggest rephrasing to indicate this is out of necessity only (while highlighting that further information on yaw time histories should be prioritised). Is this another point to include in “critical future work”, a better understanding of yaw bearing movement time histories?

More accurate information on yaw bearings would be preferable but we wouldn’t necessarily call this “critical” future work since yaw bearings (no source for this statement but hearsay) tend to cause much less issues than, say, pitch and main bearings.

Rephrased sentence to:

Since detailed time series will typically not be available, binning will often be necessary in order to calculate the life, though detailed time series would be preferable, if available.

L450 “Finally, the design of large scale yaw bearings, like that of pitch bearings, usually includes a large number of rolling elements in excess of 50 or even 100 and more per row, giving small critical angles” The critical angle will depend on both the bearing geometry/size as well as the number of rollers. Can you provide some further information or analysis to show that even for large diameter bearings this conclusion still holds? Additionally, do you have a reference for the numbers of rollers?

This is covered in the above footnote denoted 46; included a reference to that footnote

L464 “Since yaw bearings, like pitch bearings, are strongly affected by a tilting moment, a life which is around 10% shorter than that obtained with the Harris factor is to be expected.” I am not sure how the conclusion follows from the opening of this sentence, can you please elaborate for clarity.

Changed to:

Since yaw bearings, like pitch bearings, are strongly affected by a tilting moment, each of their raceways is commonly loaded around half of its circumference (Chen and Wen, 2012; Schwack et al., 2016; Menck et al., 2020; Graßmann et al., 2023), corresponding to a load zone parameter (cf. Sec. 2.1.3) of  $\epsilon = 0.4 \dots 0.6$ . With this value of  $\epsilon$ , a life which is around 10% shorter than that obtained with the Harris factor is to be expected for small oscillation amplitudes (Houpert and Menck, 2021).

L466 “If the main wind direction is truly evenly spread over all compass directions, it is permissible to use the equivalent load of a ring that rotates relative to the load for the outer ring, approximately equivalent to simply using the Harris factor” Is this because of rollers rotating internally? I am not sure I follow the logic here. In addition, this is a fairly strong claim which is being made. There will never be a perfectly circular wind rose, and no guidance is provided to serve as a cut-off for “evenly spread”. Is there any data or a short analysis which can be presented to help indicate when this is safe to apply? (At present it feels a bit hand-wavy).

The argument here is completely related to the logic of the Houpert effect, the effect of rollers is neglected for this argument. For a typical run-of-the-mill bearing, all circumferential locations of the rotating ring see similar load cycles eventually due to the ring’s rotation, whereas the stationary ring only experiences them concentrated in the same positions since the load direction is constant relative to the stationary ring. This flips for the given example: If the rotating (oscillating) ring actively follows the wind, it is always loaded in a similar position, hence it is loaded like the stationary ring in a run-of-the-mill bearing in most industrial applications. The outer ring, on the other hand, can see load all over its circumference (similar to a rotating ring in said run-of-the-mill bearing) if and only if the wind truly comes from all directions over the duration of the turbine lifespan. This is a very theoretical case and in most cases it will be more practical to assume that the outer ring also experiences concentrated loading, which is the more conservative approach.

Added a footnote:

<sup>51</sup> In this example, the behavior of a typical bearing is flipped on its head. Typical bearings in most

industrial applications experience concentrated loading on the stationary ring, since it is stationary with respect to the load. The rotating ring, on the other hand, sees loads all over its circumference (cf. Fig. 5, “rotation”: All elements on a rotating ring are loaded like the example one, only with a time shift.). In a yaw bearing in which the wind comes evenly from all directions eventually during the turbine lifespan (for example, 25% of operational time coming from north, 25% from south, 25% from south and 25% from west), the outer ring is loaded in all positions at some point and thus experiences similar damage accumulation over its circumference as a rotating ring in a typical bearing. This is a very theoretical example to illustrate potential influences of the Houpert effect, in most cases, it will be easier to simply assume concentrated loading as discussed above, which is the more conservative case.

General comment: The paper feels like it’s missing a section on “Current challenges and critical future work”. This is a topic on which it feels like we are still at the beginning of its proper scientific exploration. This review should therefore provide a roadmap for overcoming current challenges and improving the rating life predictions for oscillating bearings.

This section has been added. See current manuscript.

L470 “Most of these approaches have been proposed and used in the literature without an explanation as to when they apply. The aim of this paper was to explain when which approach can be applied.” This particular aim was achieved, but I feel there could be more guidance on how to select a method from the set of those which could be applied in any given case.

Now added in Section 4.1 as discussed above

L477 “All ISO-based approaches shorten the calculated life compared to the results using the Harris factor (or are identical to it) if applied correctly.” I am not sure if the review paper provides a detailed discussion of why this is the case, is it that oscillation always means at least one part of the raceway is worse off than in an “equivalent” rotating bearing?

This is because all ISO based approaches are a combination of the Rumbarger and Houpert effect, both of which reduce life for different reasons that are discussed in their respective sections of the review. (For the Houpert effect, this discussion wasn’t yet included, it has been added now)

Added footnote in Houpert section:

<sup>23</sup> It shortens the life in all other cases because, from a viewpoint of rolling contact fatigue, the even distribution of loads over time that is present on a rotating ring is the best case scenario for damage accumulation of a ring. Any oscillation that deviates from this loading causes increasingly more concentrated damage accumulation on selected locations of the ring. Concentrated loading (as present, for instance, on the stationary ring in a typical bearing in most industrial applications) causes a higher equivalent load, and thus a lower life, if all else is equal, than the loading of a ring that rotates relative to the load (Lundberg and Palmgren, 1947; ISO, c). Note that the Houpert effect is, however, expressed through a factor here, rather than by changing the equivalent load.

Added sentence to conclusions:

All ISO-based approaches shorten the calculated life compared to the Harris factor (or are identical to it) if applied correctly. This is because all ISO-based approaches that deviate from Harris do so because they either incorporate the Houpert or Rumbarger effect, or both, and both of these effects cause either the same life or a reduction in life compared to the Harris factor if applied correctly. ISO-based calculation approaches that increase life compared to the Harris factor are erroneous, potentially due to being overly simplified. Some phenomena described in this paper that have not yet been analyzed in the literature could slightly increase lives even for ISO-based methods.

L482 “Some results from the ISO-based approaches suggest that their predictions may be relatively close to the actual life” I’m not sure if “relatively close” was ever quantified. I assume you are referring to results in the experimental section? Please add some clarification here, or earlier in the paper.

Rephrased to:

Some experimental results from the ISO-based approaches compared well with the calculated life, suggesting that that the predictions of ISO-based methods may be relatively close to the actual life, while validations of the alternative approaches are mostly lacking.

Below, the reply to reviewer 3 (Yi Guo) can be found.

Thank you for your review. Answers and comments can be found below in blue.

This paper reviews the life calculation methods in the literature for oscillating bearings failed by roller contact fatigue. The review is thorough and has sufficient details. Places that need to be improved are below:

Using “recommendation” in the title is misleading. Please change it to “Review of life calculation methods on rolling contact fatigue for oscillating bearing with use examples” or like

We think that recommendations are an essential part of the review though and would therefore like to keep the term in the title.

Page 1, line 16, please elaborate on which conditions rolling contact fatigue will occur. Similarly, what conditions wear will appear. Do authors know the likelihood of rolling contact fatigue occurrence in wind turbine applications?

Unfortunately we know of no solid references on rolling contact fatigue occurrence in wind turbine applications. From anecdotal conversations, it doesn't seem to be a huge problem. However, with the sudden growth that turbines are still experiencing, we suspect that past failures do not necessarily inform the future: Turbines that have been running for 20 years are very different from the ones being built today and new challenges may appear. This is why it is important to validate the bearing with a calculation even if such failures were rare before.

Changed paragraph to incorporate information on wear and rolling contact fatigue risk factors:

Small oscillation amplitudes are generally seen to be a risk factor for wear, particularly in grease lubricated bearings (Behnke and Schleich, 2022; Stammer, 2020; Grebe, 2017; FVA, 2022b). However, wear can also be prevented by a number of measures (Schwack, 2020; Wandel et al., 2022) and it is definitely possible for rolling contact fatigue to occur without wear<sup>2</sup> even for oscillating amplitudes as low as  $\theta = 1^\circ$  ( $\phi = 2^\circ$ ). Rolling contact fatigue, on the other hand, is always a possible failure mechanism even in a properly designed bearing (Sadeghi et al., 2009), except for very low loads (Ioannides et al., 1999), at which there is dispute about its occurrence (Zaretsky, 2010). In many cases, such as large oscillation amplitudes, or the use of oil lubrication, wear is unlikely to occur and thus, rolling contact fatigue becomes a more important focus.

Figure 4 and Figure 5 can put sub figures side by side to use blank space.

We believe the final layout will change into a double-column layout where each of these figures can take up one column only.

In some places, language needs to be further polished. Such as combining short paragraphs, Page 14, at the end of chapter 2, please summarize and compare the various life calculation methods using tables or other forms. Please add discussions on the differences among various approaches. Table 1 is great and please expand the discussion around it.

Table 1 and Figure 7 intended to summarize (and compare) the methods, we are unsure how to extend this information. The references only give limited information themselves so interested readers would ideally look up these references themselves. As now updated, we do not necessarily recommend so. Excerpt from update Sec. 4.1:

For general users seeking to apply a life calculation, ISO related approaches are preferred to non-ISO related ones due to their simplicity and the fact that there is much more empirical basis underlying them. In case of an invariant load direction and oscillation amplitude  $\theta$ , various methods are shown in the figure. Among the ISO related ones, that by Menck can be considered to be most accurate, however, it is also complicated to apply. A less accurate (i.e., an approximated) but simpler method will be most useful for most readers. Among the approximated ISO related methods for an invariant load direction and  $\theta$ , "Bins with Palmgren-Miner" is the recommended approach due to its wide use in many areas. Among the non-ISO related methods, Table 2 gives an overview of advantages and disadvantages of each method. Since only users with very specific aims will refer to these methods, it is up to readers to take their own decision as to which of these methods, if any, to use.

Page 15, experimental validation. As discussed, appropriate experimental validation is currently lacking for the discussed life calculations methods in general. Although correct, this statement can give impressions that all the discussed calculation methods might not be reliable. I would recommend expanding this chapter by including discussions on future work – gaps in the current literature and lack of experimental validation. If experimental validation, what test needs to be performed?

New section 5 "Current challenges and critical future work" has been added to address this topic.

Chapter 4.2 and 4.3 describes examples not in wind turbines, indicated otherwise in the title. These sections can be removed.

We would like to keep these examples so that the review can also be useful for other applications outside of the wind industry, but the title has been changed accordingly.

Will the authors consider perform experiments to validate these discussed life calculation methods in the future?

We are currently in the process of performing such experiments in the scope of the HAPT2 project, among others.
