**Abstract.** Predictions of the dynamic wake meandering model (DWMM) were compared to flow measurements of a scanning Doppler lidar mounted on the nacelle of a utility-scale wind turbine. We observed that the wake meandering strength of the DWMM agrees better with the observation, if the incoming mean wind speed is used as advection velocity for the downstream transport, while a better temporal agreement is achieved with an advection velocity slower than the incoming mean wind speed.

5 A subsequent investigation of the lateral wake transport revealed differences to the passive tracer assumption of the DWMM in addition to a non-passive downstream transport reported in earlier studies. We propose to include the turbulent Schmidt number in the DWMM to improve (i) the consistency of the model physics and (ii) the prediction quality. Compared to [a benchmark the observations](#), the thus modified DWMM showed a root-mean-square error reduction by ~~52%~~ for mean velocity deficit and ~~71%~~ for the turbulence intensity, relative to the unmodified DWMM, in addition to better temporal agreement of the dynamics. This  
10 is in contrast to an error increase of ~~64% and 41%~~ ~~35% and 36%~~ if only a more accurate downstream transport velocity is used without including the turbulent Schmidt number.

## 1 Introduction

Wind turbine wakes impinging on other wind turbines within a wind farm are a significant source of power losses and they decrease the lifetime of affected wind turbines. Wake meandering is a low-frequency horizontal and vertical oscillation of the  
15 entire wake (Taylor et al., 1985). [It Large-scale turbulence of the atmospheric boundary layer \(Larsen et al., 2008\) and bluff body vortex shedding \(Medici and Alfredsson, 2006\) have been proposed as drivers of wake meandering. Wake meandering](#) affects power production due to its impact on the velocity deficit recovery, and it affects loads due to the turbulence added to the downstream flow (Larsen et al., 2013). Therefore, the modelling of wake meandering is one important aspect of wind farm development.

20 Modelling approaches for wake meandering can be grouped into two categories. The first group are computationally expensive large-eddy simulations (LES) that solve filtered flow equations at a high temporal and spatial resolutions (Mehta et al., 2014). However, their high fidelity comes at the cost of a time consuming forward integration and a difficult initialisation of the simulation. The second group are computationally inexpensive engineering models like the dynamic wake meandering model

**Figure 1.** Illustration of wake meandering at an isolated wind turbine as assumed by the dynamic wake meandering model. Large-scale turbulence of the inflow displaces the wake of a wind turbine in the spanwise direction while it is transported downstream.

(DWMM) (Larsen et al., 2008) and a statistical modelling approach (Thøgersen et al., 2017). The DWMM is based on the  
 25 assumption that the wake behaves like a passive tracer, which is transported in the vertical and horizontal directions due to  
 large-scale turbulence without (Fig. 1). The DWMM has the advantage of fast computation time and it can be initialized with  
 measurement data that are commonly available at a wind farm.

The DWMM ~~model~~ has seen validation efforts in literature, which are reviewed in the following. The underlying passive  
 30 scalar assumption of the DWMM has been accepted with the exception of the downstream transport velocity of wake me-  
 andering, which is slower than the mean wind speed (Bingöl et al., 2010; Keck et al., 2014b; Machefaux et al., 2015; Conti  
 et al., 2021; Brugger et al., 2022). Machefaux et al. (2015) additionally investigated the lateral transport velocity of the wake  
 while it is meandering, but they had no measurements of the lateral velocity of the inflow for comparison. A validation of the  
 mean velocity field and turbulence intensity predicted by the DWMM against field measurements showed good agreement and  
 revealed a sensitivity to the eddy-viscosity parametrisation used (Reinwardt et al., 2018, 2020).

35 The above-mentioned discrepancies between the passive tracer assumption of the DWMM and observed transport behaviour  
 warrant closer examination. Specifically, assuming the wake as a passive tracer in the cross-stream directions and non-passive  
 in the streamwise direction is physically inconsistent. Also, an investigation of the impact of the downstream advection velocity  
 on the predictions of the DWMM has not been carried out so far. Further, previous validation efforts for the velocity deficit  
 and the turbulence intensity predicted by the DWMM focused on validating all components of the DWMM simultaneously,  
 40 with the exception of Reinwardt et al. (2020). Here, we extend the validation of the wake meandering module of the DWMM  
 by Reinwardt et al. (2020) to the turbulence intensity. This is especially interesting, because the meandering framework of the  
 DWMM is what sets it fundamentally apart from analytical wake models.

Therefore, this paper will compare the wake dynamics modelled by the DWMM to the wake dynamics observed with  
 field measurements ~~and, further, how it affects~~. Further, we investigate how differences between modelled and observed wake  
 45 meandering dynamics affect the predictions of the DWMM for the effect of wake meandering on the mean velocity deficit and

the turbulence intensity. These research questions will be studied across a wide range of atmospheric conditions using field measurements of two pulsed Doppler LiDARs at a utility-scale wind turbine.

## 2 Methods

This section introduces first the DWMM (Sect. 2.1) followed by the research site and the instrument setup (Sect. 2.2) with which the data set for the model validation was collected (Sect. 2.3).

### 2.1 Dynamic wake meandering model

The dynamic wake meandering model (DWMM) was introduced by Larsen et al. (2007, 2008) and assumes the wake as a passive tracer that is advected by the large-scale turbulence of the atmospheric boundary layer. The model decomposes the wake into three parts: (i) a quasi-steady velocity deficit calculated with the thin shear layer approximation of the Navier-Stokes equations (Ainslie, 1988), (ii) a wake meandering part modelled as a displacement of the entire wake with the large-scale turbulence of the background flow (Larsen et al., 2008), and (iii) small-scale turbulence ~~that is superimposed on the flow field~~ based on a homogeneous Mann (1994) turbulence field that is scaled based on the local depth of the quasi-steady velocity deficit and its radial gradient. A schematic ~~illustration~~ illustration of part (i) and (ii) is on the right of Fig. 1 with the quasi-steady velocity deficit in blue and the wake displacement in black. We follow here the implementation of Reinwardt et al. (2020) for the quasi-steady velocity deficit, including their recalibration, and Bingöl et al. (2010) for the wake meandering part. The small-scale turbulence part of the DWMM is not required here, because the present investigation focuses on the wake meandering part of the DWMM. The DWMM was implemented using the commercial software Matlab for this study.

#### 2.1.1 Quasi-steady velocity deficit

The quasi-steady velocity deficit is modelled with the steady-state, axisymmetric thin shear layer approximation of the Navier-Stokes equations with an eddy-viscosity turbulence closure (Ainslie, 1988). The momentum equation is given by

$$\bar{u} \frac{\partial \bar{u}}{\partial x} + \bar{v}_r \frac{\partial \bar{u}}{\partial r} = \frac{1}{r} \frac{\partial}{\partial r} \left( \nu r \frac{\partial \bar{u}}{\partial r} \right) \quad (1)$$

and the continuity equation is given by

$$\frac{1}{r} \frac{\partial}{\partial r} (r \bar{v}_r) + \frac{\partial \bar{u}}{\partial x} = 0, \quad (2)$$

where  $\bar{u}$  is the mean wind speed in the axial direction,  $\bar{v}_r$  is the mean wind speed in the radial (or spanwise) direction,  $r$  is the radial coordinate,  $x$  is the downstream coordinate, and  $\nu$  is the eddy viscosity. The recalibrated mixing-length parametrisation of the eddy viscosity of Reinwardt et al. (2020) is given by

$$\frac{\nu}{\bar{u}_{hub} R} = k_1 F_1(\tilde{x}) T I_u + k_2 F_2(\tilde{x}) \max \left( \frac{R_w(\tilde{x})^2}{R \bar{u}_{hub}} \left| \frac{\partial U(\tilde{x})}{\partial r} \right|, \frac{R_w(\tilde{x})}{R} \left( 1 - \frac{\bar{u}_{min}(\tilde{x})}{\bar{u}_{hub}} \right) \right), \quad (3)$$

where  $\bar{u}_{hub}$  is the mean wind speed at hub height,  $\bar{u}_{min}$  is the minimum velocity of the wake,  $TI_u$  is the longitudinal turbulence intensity at hub height,  $\tilde{x} = x/R$ ,  $R$  is the rotor radius,  $R_w$  is the wake width,  $k_1 = 0.0914$  and  $k_2 = 0.0216$  are calibration constants, and  $F_1$  and  $F_2$  are empirical filter functions given by

$$F_1 = \begin{cases} 0.25\tilde{x}, & \text{for } \tilde{x} < 4, \\ 1, & \text{for } \tilde{x} \geq 4, \end{cases} \quad (4)$$

and

$$F_2 = \begin{cases} 0.035, & \text{for } \tilde{x} < 4, \\ 1 - 0.965 \exp(-0.35(0.5\tilde{x} - 2)), & \text{for } \tilde{x} \geq 4. \end{cases} \quad (5)$$

The system of partial differential equations given by Eq. (1) and Eq. (2) was solved on an isotropic grid with a resolution of  $0.01D$  spanning  $10D$  from the origin at the nacelle using the method of Crank and Nicolson (1947). The inner boundary condition is  $V(r = 0) = 0$ , and the outer boundary condition is  $U(r = 10D) = u_{hub}$ . The initial condition at  $x = 0$  is introduced in the next section.

### 2.1.2 Initial velocity deficit at the rotor plane

The thin shear layer equations (Eq. 1 and Eq. 2) omit the pressure gradient terms. The effect of the pressure gradients is considered negligible at a distance of  $3D$  (Madsen et al., 2010). Therefore, the boundary condition at  $x = 0$  is designed to account for the effect of the neglected pressure gradient by including expansion and deceleration of the flow at the rotor disc such that the resulting flow field after  $3D$  is accurately represented. The initial velocity deficit is iteratively given by

$$\bar{u}_{ini}(r_{w,i}) = \bar{u}_{hub}(1 - (1 + f_u)\bar{a}) \quad (6)$$

and

$$r_{w,i} = r_i \sqrt{\frac{1 - \bar{a}}{1 - (1 + f_R)\bar{a}}} \quad (7)$$

with  $f_u = 1.1$ ,  $f_R = 0.98$ ,  $\bar{a}$  is the induction factor averaged along all radial positions,  $r_i$  is the rotor radius at position  $i$ , and  $r_{w,i}$  is the wake radius at position  $i$  (Keck et al., 2013). The induction factor is computed from the thrust coefficient of the wind turbine ( $C_T$ ) by using the relationship

$$C_T = 4\bar{a}(1 - \bar{a}), \quad (8)$$

where  $\bar{a}$  is assumed to be constant across the rotor area. The assumption-thrust coefficient is selected from Fig A1 based on  $u_{hub}$ . The assumption of a constant induction factor is necessary because the radial distribution of the induction factor its radial distribution is not available to us for the wind turbine at the research site. However, testing with two different induction factor distributions of model wind turbines shown in literature (scaled so that they yield the same mean induction factor) showed that the two initial velocity deficits at  $x > 4D$  had a mean absolute difference of 0.9% with a maximum of 1.5% based on the mean wind speed for the wind speed range covered in the results.

### 2.1.3 Wake meandering

The DWMM uses the hypothesis that the wake can be modelled as a passive tracer that is transported by the large-scale turbulence structures of the atmospheric boundary layer. The process can be imagined as a continuous sequence of velocity deficits emitted by the wind turbine that are passively transported by the large-scale turbulence (Larsen et al., 2008). Therefore, a suitable description of the turbulence field is required. We depart here from the implementation of Reinhardt et al. (2020), who used a Kaimal spectrum to generate a stochastic turbulence field, and instead we will follow the approach of Bingöl et al. (2010) that is more suitable for a direct comparison with wake measurements. They adopted Taylor's frozen turbulence hypothesis (Taylor, 1938) and assumed that the large-scale turbulence is correlated across the rotor area. The instantaneous wake position is then given by

$$110 \quad \frac{dx_{pre}(t, \Delta T)}{dt} = \bar{u}_a, \quad (9)$$

$$\frac{dy_{pre}(t, \Delta T)}{dt} = v(t, \Delta T), \quad (10)$$

and

$$\frac{dz_{pre}(t, \Delta T)}{dt} = w(t, \Delta T), \quad (11)$$

115 where the subscript "pre" stands for prediction,  $\bar{u}_a$  is the downstream advection velocity (also called downstream transport velocity),  $v$  and  $w$  are the large-scale lateral and vertical turbulent velocity fluctuations,  $t$  is the time ~~of velocity deficit "emission"~~ when a quasi-steady velocity deficit arrives at a downstream location, and  $\Delta T$  is the time ~~that has elapsed since a specific velocity deficit "emission"~~ delay until the emitted velocity deficit has reached a given downstream distance. Using the lateral velocity at the turbine location for the right-hand side of Eq. (10), the instantaneous wake center position in the horizontal plane is given by

$$120 \quad y_{pre}(x, t) = v(t - \Delta T(x))\Delta T(x), \quad (12)$$

where  $\Delta T$  was expressed as a function of the downstream distance  $x$  with

$$\Delta T(x) = \int_0^x \frac{dx}{\bar{u}_a(x)}. \quad (13)$$

We will compare two assumptions for the downstream advection velocity in the results: (1) the advection velocity is the same as mean wind speed with  $\bar{u}_a(x) = \bar{u}_{hub}$ , and (2) the advection velocity is given by the average of the mean wind speed and mean velocity at the wake center with

$$\bar{u}_a(x) = 0.5(\bar{u}_{cen}(x) + \bar{u}_{hub}) \quad (14)$$

as proposed by Cheng and Porté-Agel (2018). For the latter, the mean velocity at the wake center  $\bar{u}_{cen}(x)$  is computed with the analytical wake model of Bastankhah and Porté-Agel (2016) (see Eq. (A2) in appendix B A). Assumption (1) is following the simplified DWMM in Larsen et al. (2008). Assumption (2) is an improvement on Keck (2015), who assumed that the downstream advection velocity is a constant 80% of the mean wind speed.

The vertical component of wake meandering cannot be computed directly, because measurements for the right-hand side of Eq. (11) are not available. Instead, we assume that the vertical wake meandering can be modelled to be proportional to the lateral wake meandering with

$$z_{pre}(x, t) = r_{yz} y_{pre}(x, t), \quad (15)$$

where the factor  $r_{yz}$  is the ratio between the horizontal and the vertical wake meandering strength.

We assume that a suitable choice of  $r_{yz}$  is the ratio of lateral to vertical turbulence intensity. For a purely shear driven ABL, ratios of  $TI_v/TI_u$  and  $TI_w/TI_v$  are about 0.5, while for a purely convective ABL  $TI_v \approx TI_u < TI_w$  above the surface layer and  $TI_v \approx TI_u > TI_w$  within the surface layer (Moeng and Sullivan, 1994). Wind tunnel experiments with purely shear-driven flows showed that wake meandering in the vertical direction had a smaller amplitude than the lateral direction (España et al., 2012; Bastankhah and Porté-Agel, 2017), which supports the assumed proportionality to the turbulence intensity ratios. Keck et al. (2014a) presented ratios for vertical to lateral wake meandering of approximately 0.6, 0.8, and 0.9 for stable, neutral, and unstable conditions, respectively. We do not have direct measurements of  $TI_w/TI_v$  and the data available to us from a nearby meteorological tower was not suitable to determine the boundary layer state. Therefore, we assume  $r_{yz} = 0.8$  as an average ratio.

Further, Eq. (15) implies a perfect correlation between  $y_{pre}$  and  $z_{pre}$ , which might not be the case in reality. However, randomly rearranging  $z_{pre}$  changed the slopes of the linear regressions shown in Sect. 3.2 by less than 0.02 (no detectable change for the intercept and the correlation coefficient) and, therefore, does not affect the drawn conclusions.

## 2.2 Research site and measurement setup

The research site and the measurement setup is the same as reported in Brugger et al. (2022). The setup was implemented between 19 August 2017 and 2 October 2017. Quality assurance and data selection criteria are summarized at the beginning of Sect. 3.

The site consists of an isolated wind turbine located at Kirkwood Community Collage in Cedar Rapids, Iowa (Fig. 2). The wind turbine is a 2.5 MW Liberty C96 from Clipper Windpower with a hub height of  $z_{hub} = 79$  m and a rotor diameter of  $D = 96$  m. The area in the vicinity of the wind turbine is urbanized with some agricultural farmland to the south and east. Data from the supervisory control and data acquisition (SCADA) system of the wind turbine are available to us with a 10-minute resolution.

We installed two pulsed Doppler LiDARs on the roof of the nacelle (Fig. 3a). A Doppler LiDAR emits infrared laser pulses that are scattered by aerosols within the atmosphere. The backscattered light receives a frequency shift due to the Doppler effect caused by the movement of the aerosols. Assuming that aerosols are transported by the wind, the line-of-sight velocity of the

**Figure 2.** Satellite image of the measurement site with the location of the wind turbine (© Google Earth). The wind turbine coordinates are  $41.9165^\circ$  latitude and  $-91.6508^\circ$  longitude.

air along the laser beam can be estimated from the frequency shift detected by the instrument. The instruments were Stream Line models from Halo Photonics Ltd. (Worcestershire, UK). ~~The instruments were programmed to sample the velocity with a temporal frequency of~~

165 The Doppler LiDAR mounted towards the rear of the nacelle was used to scan the wake. It was configured to average 3000 pulses per velocity estimate and use six points per range gate. This leads to an effective sampling frequency of approximately 3 Hz and spatial resolution of 18 m along the laser beam.

170 ~~The Doppler LiDAR mounted towards the rear of the nacelle~~ A signal-to-noise ratio (SNR) threshold of  $-14$  dB is used to reject low quality Doppler LiDAR measurements, resulting in a theoretical standard deviation of the Doppler estimate of  $0.3 \text{ m s}^{-1}$  as the upper limit for the uncertainty (Pearson et al., 2009). It was programmed to perform 230 successive Plan Position Indicator (PPI) scans in the downstream direction with an opening angle of  $\pm 12^\circ$  and an azimuth step of  $2^\circ$  to capture

the wake (Fig. 3). Each individual PPI sweep with the return to the starting position took 7.2 s and the full scan was completed in approximately 28.4 minutes. The scans were designed to be slightly shorter than the 30 minute period allocated in the scan schedule to ensure smooth operation of the measurements. Because the scanner head was moving during the sampling, we assume that the spatial uncertainty of a measurement is equal to its travel distance ( $2^\circ$ ).

175 Simultaneously, the front mounted Doppler LiDAR was used to measure the inflow. It was configured to average 5000 pulses per velocity estimate and use six points per range gate. It was programmed to measure the lateral velocity component with a horizontal, fixed beam at a  $90^\circ$  to the rotor axis for a period of 14 minutes (for the remainder of the 30 minute period, it measured with a fixed beam parallel to the rotor axis upstream, but those measurements ~~are not used here~~ were only used to validate the SCADA data). This scan pattern of the two Doppler LiDARs was scheduled to begin every second hour at the  
180 half hour mark. The theoretical uncertainty of the radial velocity was estimated based on the recorded SNR using Eq. (2) from Pearson et al. (2009), but it was smaller than the velocity resolution of the instrument due to the proximity of the range gate from which the data is used (see Sect. 2.3.1). Therefore, the velocity resolution will be assumed as the uncertainty of the lateral velocity ( $0.038 \text{ m s}^{-1}$ ).

## 2.3 Model inputs and reference data

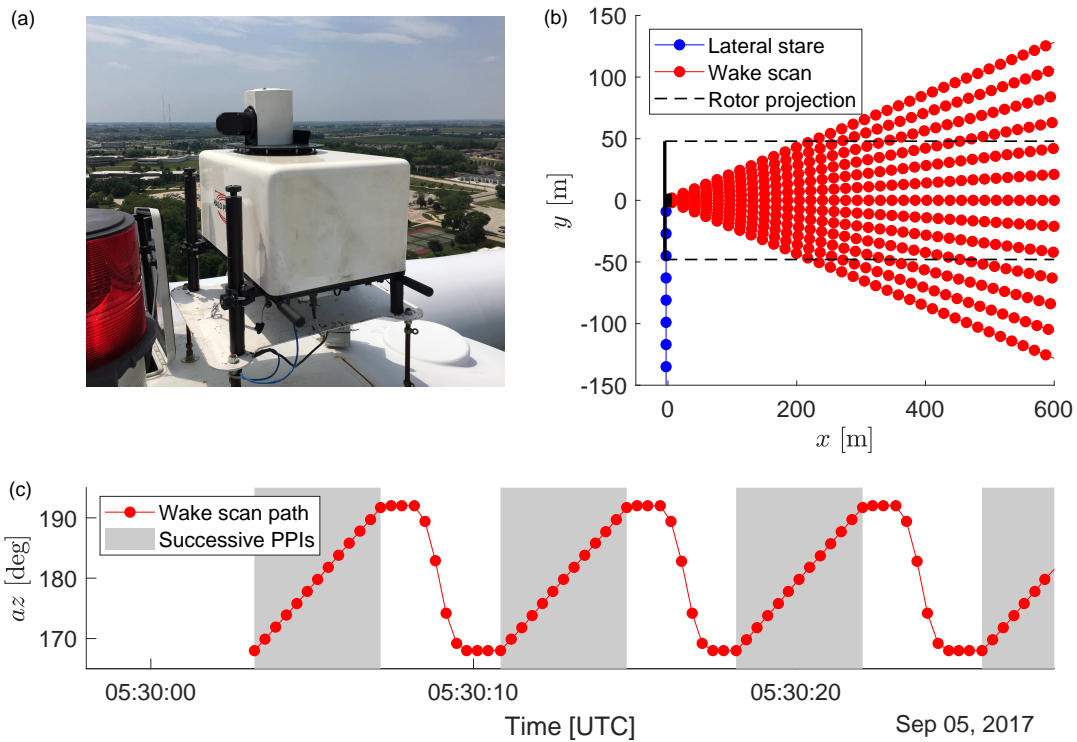

185 The input values of the DWMM and the reference of the validation use data from separate measurement instruments to keep them independent. The model input is generated from the SCADA data and the measurements of the front-mounted Doppler LiDAR. The measurements of the rear-mounted Doppler LiDAR are used as the reference for the validation.

### 2.3.1 Model inputs

The input variables of the DWMM and the measurements from which they are taken are listed below:

- 190 –  $\bar{u}_{hub}$  is the mean wind speed at hub height. It is measured by a cup anemometer located on the roof of the wind turbine and reported in the SCADA data. Because the SCADA data has a 10-minute resolution, we use the average of a 20-minute period for the averaging period of the mean wind speed, which is longer than the 14-minute measurement period of the front-mounted Doppler LiDAR. Based on a comparison to the upstream stare of the front-mounted Doppler lidar, we assume that  $\bar{u}_{hub}$  has an uncertainty of  $0.25 \text{ m s}^{-1}$  quantified as the root-mean-square error.
- 195 –  $v(t)$  is the time series of the large-scale lateral velocity of the inflow. It is generated from the measurements of the front-mounted Doppler LiDAR using the range gate at a distance of 117 m, which is the closest range gate that is not affected by the rotor. A ~~linear trend mean~~ is removed and a low-pass filter with a threshold of  $\beta\Delta T$  with  $\beta = 0.8$  is applied to isolate the large-scale turbulence fluctuations (Cheng and Porté-Agel, 2018). ~~This~~ In the spatial domain, this threshold of the low-pass filter is proportional to the downstream distance  $x$  and it is considerably larger than the rotor  
200 diameter ~~and it is therefore,~~ which makes it reasonable to assumed that  $v(t)$  is representative for the full rotor area. ~~A trend is removed from  $v(t)$  instead of the mean to remove non-stationary effects, like a steady change of the wind direction over a 14-minute period, that are not considered wake meandering.~~ Further, the lateral turbulence intensity

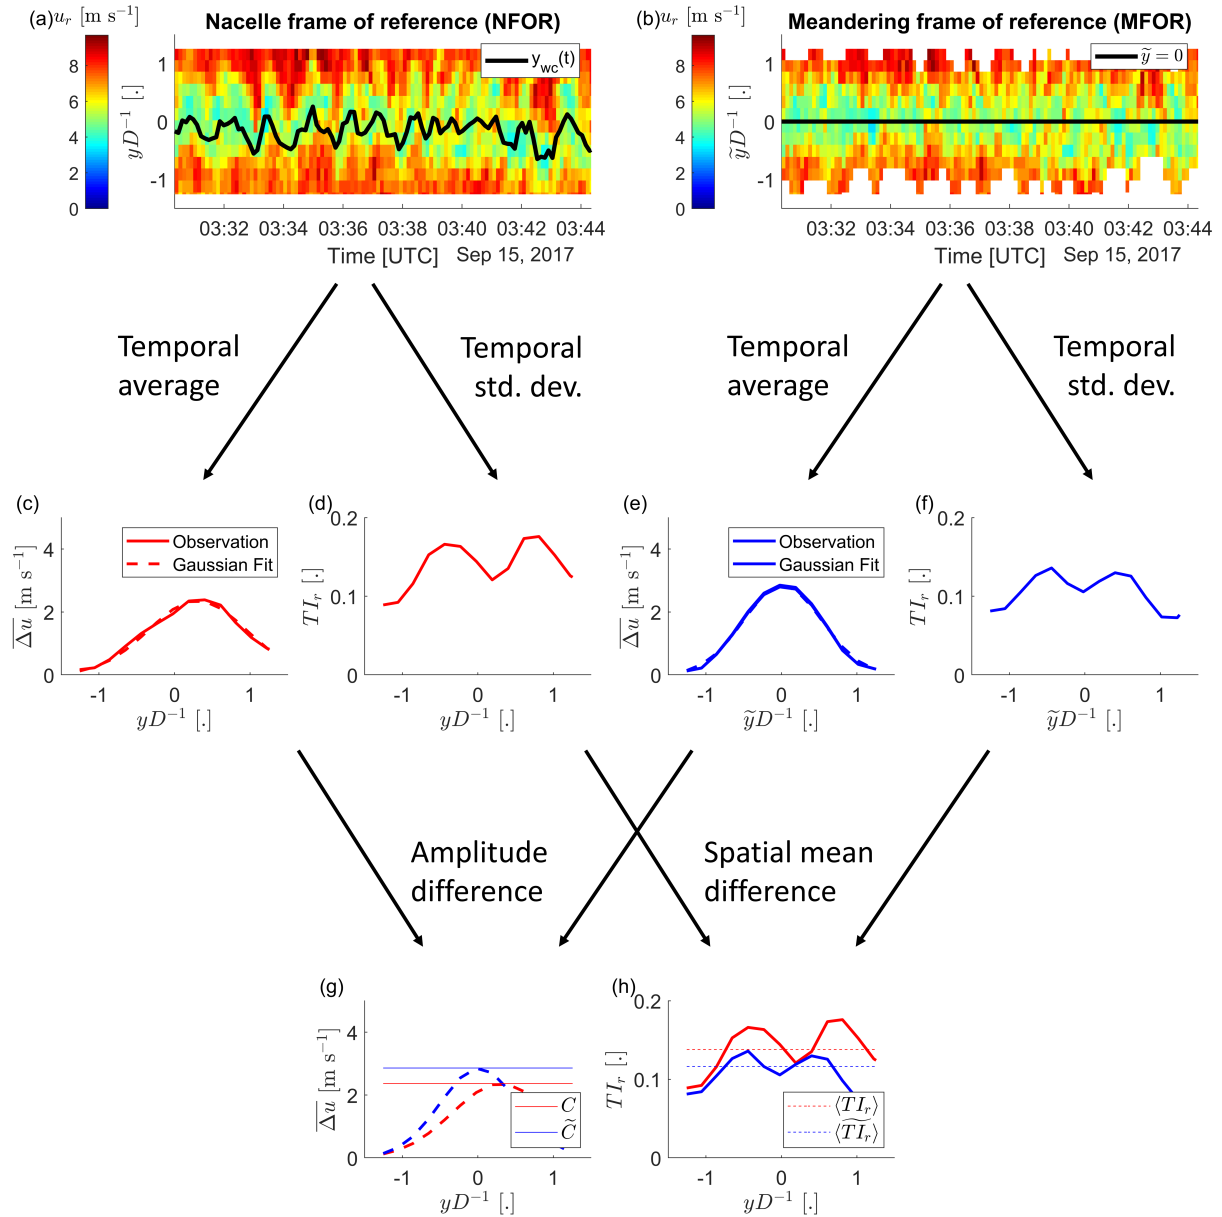

**Figure 3.** Photo of the front-mounted Doppler LiDAR on the nacelle of the wind turbine (a). Scan patterns of the nacelle mounted Doppler LiDARs viewed from top (b). Wake scans of the rear-mounted Doppler LiDAR (red) were accompanied by measurements in a lateral staring mode of the front-mounted Doppler LiDAR (blue). LiDAR beams are shown as lines with range gate centers indicated as points. The wind turbine is stylized in black and the rotor-edge projection in the wind direction is indicated with black dashed lines. The bottom panel shows the scanner path for a section of a wake scan (c), where the grey area indicates the successive PPIs that, together, become a wake scan. Figure adapted from Brugger et al. (2022) with changes under the Creative Commons Attribution 4.0 License (<https://creativecommons.org/licenses/by/4.0/>).

$(TI_v)$  and the integral time scale ( $T_{i,v}$ ) are computed from  $v(t)$  prior to the low-pass filtering. A proportionality between longitudinal and lateral turbulence intensity with  $TI_u = \frac{3}{2}TI_v$  is assumed.

205 –  $C_T$  is the wind speed dependent thrust coefficient of the wind turbine. It is selected from the thrust curve in Fig. A1 based on  $\bar{u}_{hub}$ .

### 2.3.2 Reference data set

The instantaneous wake center position, the turbulence intensity added by wake meandering, and the reduction of the mean velocity deficit due to wake meandering are extracted from the measurements of the rear mounted Doppler LiDAR. The  
 210 processing steps listed below and illustrated in Fig. 4 are similar to those in Brugger et al. (2022):

**Figure 4.** The data processing steps to quantify the effect of wake meandering on the mean velocity deficit and the turbulence intensity are illustrated for an example at a downstream distance of  $x = 5D$ . The instantaneous velocity deficit in the nacelle frame of reference (a) and meandering frame of reference (b) have a temporal average (c, e) and standard deviation (d, f) applied. The reduction of the mean velocity deficit due to wake meandering is then quantified as amplitude difference (g) of two Gaussian fits to the two velocity deficits in (c) and (e). The turbulence intensity added by wake meandering is quantified as the spatially averaged difference in turbulence intensity (h).

1. A signal-to-noise ratio (SNR) threshold of  $-17$  dB is used to reject low quality Doppler LiDAR measurements (Pearson et al., 2009)

—

215 2. The remaining line-of-sight velocities are gridded on a polar coordinate system  $u_r(\phi, r, t)$  with an azimuth ( $\phi$ ) resolution of  $2^\circ$ , a radial ( $r$ ) resolution of 18 m, and a time step ( $t$ ) aligning with the PPIs of the wake scans. The  $az$  positions of the LiDAR scans and the  $\phi$  positions of the polar coordinate system can have a difference of  $0.2^\circ$  towards the end of a PPI resulting from the acceleration phase of the scanner head, small variations of the scanner behaviour, and fluctuations of the sampling frequency. Multiple measurements are available for the outside grid points due to a short resting time of the scanner at the turn-around point and the measurements closest in time are used at those grid points.

220 3. The transformation to a Cartesian coordinate system is made using  $y = r \sin^{-1}(\phi)$  and  $x = \langle r \cos^{-1}(\phi) \rangle$ , where the angle brackets indicate the lateral averaging.

4. An instantaneous velocity deficit is computed with  $\Delta u_r(x, y, t) = \bar{u}_{hub} - u_r(x, y, t)$ . This approach maps all measurements during a PPI on a single time stamp neglecting the travel time of the scanner head.

5. The instantaneous position of the wake center is detected with the centroid of the velocity deficit with

$$y_{wc}(x, t) = \frac{\sum_y y \Delta u_r(x, y, t)}{\sum_y \Delta u_r(x, y, t)}, \quad (16)$$

225 where the subscript "wc" stands for wake centroid and negative values of  $\Delta u_r(x, y, t)$  are set to zero.

6. The instantaneous velocity deficit in the meandering frame of reference ( $\Delta u_r(x, \tilde{y}, t)$ ) is computed by transformation of the lateral coordinate with  $\tilde{y} = y - y_{wc}$  and interpolated on the original  $y$  grid points.

230 7. The temporal mean and the standard deviation of  $\Delta u_r(x, y, t)$  and  $\Delta u_r(x, \tilde{y}, t)$  provide profiles of the mean velocity deficit and the turbulence intensity in the nacelle frame of reference (NFOR) and the meandering frame of reference (MFOR), respectively. The NFOR is identical to a fixed frame of reference here, because data was selected to have no yaw activity of the wind turbine.

8. The reduction of the mean velocity deficit due to wake meandering is then quantified by the amplitude difference of two Gaussian functions fitted to the mean velocity deficit in the NFOR and the MFOR, respectively. The difference will be denoted as  $\tilde{C} - C$  where  $C$  ( $\tilde{C}$ ) is the amplitude of the Gaussian function in the NFOR (MFOR).

235 9. The turbulence added by wake meandering is quantified by the laterally averaged difference in turbulence intensity between the NROR and the MFOR. It will be denoted as  $\langle TI_u - \tilde{TI}_u \rangle$ .

10. Lastly, a temporal linear trend mean is also removed  $y_{wc}(x, t)$  and a low-pass filter is applied to make it comparable to  $y_{pre}(x, t)$  of the DWMM that is based on the detrended and low-pass filtered  $v(t)$ . ~~Note that  $\tilde{C} - C$  and  $\langle TI_u - \tilde{TI}_u \rangle$  still include non-stationary effects and we will deal with that in Sect. ??.~~

240 The above processing steps are applied for downstream distances between  $xD^{-1} = 3$  and  $xD^{-1} = 7$ . The Doppler lidar's field of view and the double-peak shape of velocity deficit in the near-wake were problems for the detection of  $y_{wc}$  for  $xD^{-1} < 3$ , and the lateral resolution of the lidar scans became coarser than 10 m for  $xD^{-1} > 7$ . Some parts of the results will focus on a downstream distance of  $x = 5D$ , because the scanning cone has an ideal width of  $2D$  there and  $5D$  is typical distance between wind turbines in onshore wind farms.

### 245 2.3.3 Error propagation of the measurement uncertainty

The measurement uncertainties are propagated to the model predictions and the reference data with a Monte Carlo method. We created 100 resamples of the measurement data with random fluctuations added that were drawn from a normal distribution with a standard deviation equal to the measurement uncertainty (except for the azimuth for which a uniform distribution was used). The model predictions and the wake quantities were computed for each of the 100 resamples and the propagated measurement uncertainty was quantified as the root-mean-square error. If results are normalized in Sect. 3, we apply the error propagation rules for a division as a last step.

250

In case of the DWMM, the Monte Carlo approach was implemented in two stages. First, we estimated the uncertainty of  $y_{pre}$  with the Monte Carlo approach based on the uncertainties of  $v$  and  $\bar{u}_{hub}$ . Then, we estimated the uncertainty of the mean velocity deficit and the added turbulence intensity with a second Monte Carlo approach based on the uncertainties of  $y_{pre}$  and  $\bar{u}_{hub}$ .

## 3 Results

The first part of the results will focus on the modelling of wake meandering itself, while the second part will focus on the validation of the predicted effects that wake meandering has on the mean velocity deficit and the turbulence intensity. A set of 43 cases, each covering an approximately 14-minute period, was selected from the measurement data of the campaign. The selection criteria were a mean wind speed above  $5 \text{ m s}^{-1}$ , no yaw movement of the wind turbine, a sufficient mean SNR of the Doppler lidar, and a wake within the Doppler lidar's scanning cone. The 43 cases cover a wind speed range from  $5 \text{ m s}^{-1}$  to  $11 \text{ m s}^{-1}$ , turbulence intensities of the lateral velocity component up to 8% (for higher turbulence intensities, the wake is not covered by the Doppler LiDARs scanning cone due to very strong wake meandering). The selection criteria and the data set are identical to Brugger et al. (2022).

### 265 3.1 **Testing of the passive scalar assumption of the DWMM**

First, the predictions of the instantaneous wake center positions will be validated. The root-mean-square error (RMSE) and the correlation coefficient between the predicted wake center position (Eq. 12) and the observed wake center position (Eq. 16) will be used as quality metrics. The observed wake center position has been ~~detrended and~~ low-pass filtered with the same filter threshold as the input of the DWMM for comparability. The results of the evaluation at  $x = 5D$  are shown in Fig. 5. They have a general trend of an increasing correlation and a decreasing normalized RMSE with  $T_{i,v}\Delta T^{-1}$ . The ratio  $T_{i,v}\Delta T^{-1}$

270

quantifies the rate of evolution of the turbulent wind field during the time of downstream advection (or in other words how well the Taylor’s frozen turbulence hypothesis holds). This behaviour is in agreement with the recommendation that for large downstream distances, the spatial variability of the large-scale turbulence components should be taken into account (Larsen et al., 2008), which is supported by the results of a previous data analysis (Brugger et al., 2022).

275 Next, we will investigate the effect of the downstream advection velocity on the predicted wake-center positions. We will compare predictions using the reduced downstream advection velocity given by Eq. (14) with predictions using the mean wind speed of the inflow as the downstream advection velocity. The effect of the choice of advection velocities on the correlation coefficient is shown in Fig. 6a. ~~Using the reduced advection velocity~~ It shows that using  $\bar{u}_a$  instead of  $\bar{u}_{hub}$  improved the correlation between predictions and observations for  $x < 5D$ , indicating better temporal alignment for the predictions using  
280 the reduced downstream advection velocity. Removing a temporal trend instead of the mean from  $y_{pre}$  and  $y_{wc}$  prior to the correlation would lead to a twice as large improvement of the correlation (we do not remove a linear trend here, because it is problematic for Sect. 3.2 where we cannot remove a trend from the observations). This can be explained by non-steady effects like a change of the wind direction, which contribute to the correlation, but do not depend on the downstream transport. No systematic effect on the correlation is observed beyond  $5D$ , which can be explained by  $\bar{u}_a(x)$  approaching  $\bar{u}_{hub}$  with increasing  
285  $x$  and the decorrelation of the two turbulent signals with increasing separation.

Despite the increase in correlation coefficient, using  $\bar{u}_a$  had a detrimental effect on the normalized RMSE (Fig. 6b). This will be investigated in more detail in the following section.

### 3.1.1 Overestimation of the wake meandering strength

It was previously observed that using  $\bar{u}_a$  as the advection velocity increases the RSME despite having a higher correlation with  
290 the observation. Analysing several cases visually, we observed that the predictions had in many cases a too large amplitude of the wake displacement compared to the observations. Figure 7 shows three examples from the data set to illustrate the behaviour. It is apparent that the better temporal alignment of the predictions using  $\bar{u}_a$  is accompanied by an overestimation of the wake displacement compared to the predictions with  $\bar{u}_{hub}$ . Quantifying the overestimation with the difference in wake meandering strength for the whole data set, it becomes clear that this is a systematic bias that is introduced by the reduced  
295 advection velocity (compare Fig. 8a and Fig. 8b).

Better temporal agreement of the DWMM when using a downstream advection velocity slower than the mean wind speed was observed in several studies (Bingöl et al., 2010; Keck et al., 2014b; Machefaux et al., 2015). However, a subsequent overestimation of the wake meandering strength has not been reported as a problem so far. While Keck et al. (2014a) showed in their Fig. 3 that the lateral wake meandering strength predicted by the DWMM increases with a slower downstream transport  
300 velocity for  $x < 10D$ , they did not further investigate the matter (possibly due to a scaling of the wake meandering strength at a later stage of their DWMM implementation). In a previous validation of the passive scalar assumption by Bingöl et al. (2010), this phenomenon was not reported, but a visual inspection of their Fig. 8 suggests that three of their four cases also exhibit a larger displacement of the wake center position in the DWMM predictions compared to the wake measurements. Trujillo et al. (2011) showed an example case in their Fig. 5 which we digitized (linearly interpolating the parts that were obstructed

**Figure 5.** The correlation coefficient (a) and normalized root-mean-square error (b) between the wake center position predicted by the dynamic wake meandering model ( $y_{pre}$ , Eq. 12) and the observed wake position by the wake scanning Doppler lidar ( $y_{wc}$ , Eq. 16) at a downstream distance of  $5D$  from the wind turbine. The ratio between the integral time scale of lateral velocity ( $T_{i,v}$ ) and the time delay due to downstream advection ( $\Delta T^{-1}$ ) quantifies the rate of evolution of the turbulent wind field during the time of downstream advection. The error bars show the standard deviation of the propagated measurement uncertainty. The 95% confidence bounds of the linear fit show the statistical uncertainty due to the scatter of the data points.

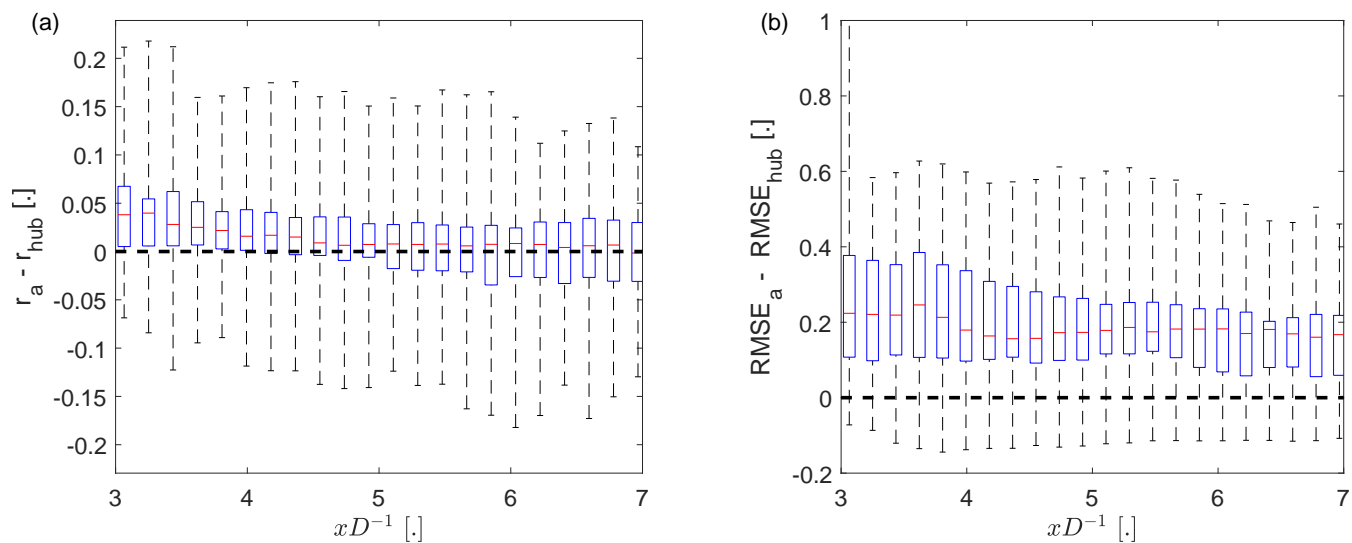

305 by other plot elements) and found similar displacements of the wake center position for the predictions and the observations. However, the description of their data processing mentions low-pass filtering only for the modelled wake of the DWMM and not the observed wake, which could mask the overestimation. Other validations might not have observed this issue previously, because using the mean wind speed for the downstream advection and a temporally averaged validation approach masks the issue (Reinwardt et al., 2018, 2020; Conti et al., 2021).

310 Based on our own findings and the literature review, we believe that the discrepancy between temporal agreement and wake meandering strength points towards a short-coming of the ~~passive-scalar~~ passive-tracer assumption of the DWMM. In the following section, we will provide a hypothesis to address this problem. Other possible explanations for the overestimation that were tested on the data and rejected are listed in ~~Appendix C~~ Appendix B.

### 3.1.2 Improvement of the DWMM to account for momentum transport

315 We hypothesize that the transport of the wake with large-scale turbulence is more akin to the transport of momentum than the transport of a passive tracer and that, subsequently, the turbulent Schmidt number should be considered in the modelling of wake meandering. The turbulent Schmidt number characterises the ratio between the turbulent transport of momentum and the turbulent transport of passive scalars. Previous experiments indicated that momentum is transported less efficiently than scalars

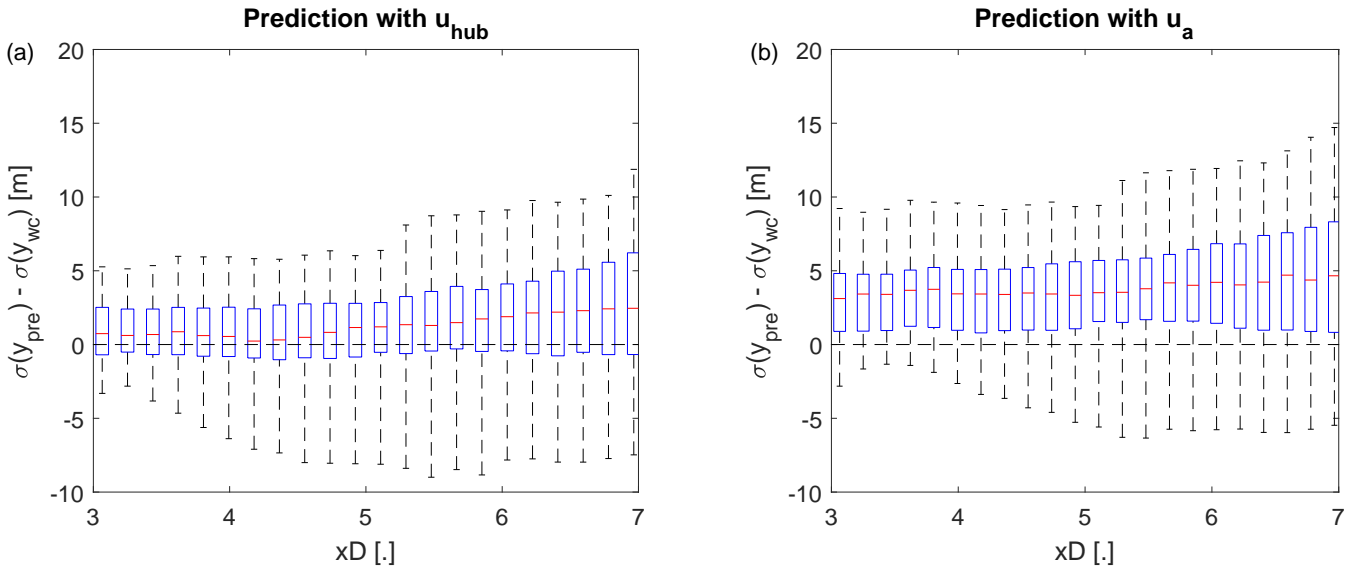

**Figure 6.** The effect of the downstream advection velocity on the correlation coefficient (a) and on the normalized root-mean-square error (b) between  $y_{pre}$  and  $y_{wc}$  as a function of the downstream distance. The subscript "a" ("hub") indicates  $\bar{u}_a$  ( $\bar{u}_{hub}$ ) as downstream advection velocity. The whiskers show the range of the data, the top and bottom of the blue box indicating the 25th and 75th percentile, and the red center marker showing the median.

**Figure 7.** The time series of the observed and the predicted wake center positions at  $x = 5D$  for three example cases, which were selected for their high correlation between reference and prediction. The predictions are shown for  $\bar{u}_{hub}$  (dashed blue) and  $\bar{u}_a$  (solid blue) as the downstream transport velocity. The reference from the observations is shown in black.

**Figure 8.** Error between observed and predicted wake meandering strength with  $\bar{u}_{hub}$  (a) and  $\bar{u}_a$  (b) as downstream advection velocity. The whiskers show the range of the data, the top and bottom of the blue box indicate the 25th and 75th percentile, and the red center marker shows the median.

in turbulent wakes (Reynolds, 1976; Antonia et al., 1993). First, we provide support for this hypothesis by comparing observed  
 320 transport behaviour of the wake with the expectation of a passive scalar. Then we include the turbulent Schmidt number into  
 the DWMM and compare those new predictions with the observations.

We use the diffusion theory of Taylor (1922) to compare the observed transport of wake meandering with the expected  
 transport of a scalar. Cheng and Porté-Agel (2018) adapted the diffusion theory from a point source to an area source for wind  
 turbine wakes. The standard deviation of a lateral profile of a scalar concentration in a wake at  $\Delta x$  downstream of the virtual  
 325 point source is then given by

$$\sigma_{y,scalar} = \langle v^2 \rangle^{0.5} \frac{\Delta x}{\bar{u}_a}, \quad (17)$$

where  $\langle v^2 \rangle^{0.5}$  is the standard deviation of the lateral air velocity. If momentum is considered, which is transported less efficient  
 than a scalar in a wake (Reynolds, 1976), this expression becomes

$$\sigma_{y,wake} = \sqrt{Sc_t} \langle v^2 \rangle^{0.5} \frac{\Delta x}{\bar{u}_a}, \quad (18)$$

330 where  $Sc_t$  is the turbulent Schmidt number. We assume that the standard deviation of the lateral transport velocity of the  
 wake centroid can be expressed as  $\langle v_{wake}^2 \rangle^{0.5} = \sqrt{Sc_t} \langle v^2 \rangle^{0.5}$ . With this assumption, we can determine the turbulent Schmidt  
 number of wake meandering from the ratio of the standard deviation of the lateral velocity to the standard deviation of the  
 lateral velocity of the wake centroid:

$$Sc_t = \left( \langle v_{wake}^2 \rangle^{0.5} \langle v^2 \rangle^{-0.5} \right)^2. \quad (19)$$

**Figure 9.** Turbulent Schmidt numbers of wake meandering (Eq. 19) as function of the downstream distance from the wind turbine. The whiskers show the range of the data, the top and bottom of the blue box indicate the 25th and 75th percentile, and the red center marker shows the median.

335 The lateral transport velocity of the wake center ( $v_{wake}$ ) can be determined from the lateral displacement of the wake center position following a method of Machefaux et al. (2015). First, the time lag  $\Delta t$  between  $v(t)$  and the wake center position  $y_{wc}(t)$  for a given downstream distance is determined with a cross-correlation. We do not use Eq. (13) to compute the time delay to make no assumptions on the downstream transport velocity here. Then, the lateral transport velocity of the wake center is estimated with  $v_{wake} = y_{wc}/\Delta t$ . If the cross-correlation for determining  $\Delta t$  is lower than 0.8 the estimate of  $v_{wake}$  is rejected.

340 The turbulent Schmidt number was determined with Eq. (19) using  $v$  measured by the front-mounted Doppler lidar as described in Sect. 2.3.1 and  $v_{wake}$  determined as described in the previous paragraph. Both time series were low-pass filtered and detrended to make them comparable. The results in Fig. 9 show that the turbulent Schmidt numbers of wake meandering are smaller than unity for the majority of the data set. The average of the observed  $Sc_t$  is ~~0.68~~, which 0.71, which is close to 0.7 used by Cheng and Porté-Agel (2018) for wind turbine wakes based on Reynolds (1976). This suggests that wake meandering

345 is more akin to the transport of momentum than the transport of a passive scalar. Using an average over multiple range gates to determine  $v$  to mirror the spatial averaging of the wake center detection changes the average  $Sc_t$  to 0.69. Down sampling  $v$  to the temporal resolution of  $y_{wc}$  prior to low-pass filtering has also only a small effect on the results by changing the average  $Sc_t$  to 0.64.

Following our hypothesis, we modified the DWMM to account for a reduced momentum transport efficiency by including  $\sqrt{Sc_t}$  with constant  $Sc_t = 0.7$  in Eq. (12). The results are shown in Fig. 10. Including  $Sc_t$  reconciled ~~81~~89% of the overestimation of the wake meandering strength.

### 3.2 Validation of the modified DWMM

The second part of the results will ~~compare the original DWMM and the modified~~ validate the predictions of the DWMM for the effect of wake meandering on the mean velocity deficit and the added turbulence intensity. The DWMM will be compared

**Figure 10.** Observed wake meandering strength and predicted wake meandering strength of the DWMM. **Blue indicates** The left panel (a) shows the DWMM with the passive scalar assumption and red indicates the right panel (b) shows the DWMM modified with turbulent Schmidt number to account for a less efficient momentum transport. The errorbars show the standard deviation of the measurement uncertainty propagated to the predicted and observed wake meandering strength, respectively. The 95% confidence bounds of the linear fit show the statistical uncertainty due to the scatter of the predictions.

355 to the observations in Sect. 3.1.2 and the impact of the previously proposed modification will be investigated in Sect. ??. The validation is focused on the effect of wake meandering instead of the absolute values, because the absolute values can be predicted with an analytical model (e.g Qian and Ishihara, 2018) and the ability to predict the effect of wake meandering sets the DWMM apart.

### 3.2.1 **Benchmark data for the model validation**

360 **Before going into the validation, a benchmark is defined. The motivation for this is that the reference data set as introduced in Sect. 2.3.2 includes the effects of a non-stationary flow (e.g. turbulence scales that are longer than the 14-minute measurement period for each case or a steadily changing wind direction for synoptic reasons) and measurement errors that are not part of the DWMM and thus should be removed for a fair comparison. The goal of the benchmark is to isolate the part of the observations that can be explained by the framework of the DWMM.**

365 **3.2.1 Prediction of the mean velocity deficit and the turbulence intensity**

As the benchmark, we use the observed mean velocity deficit in the MFOR, which is spatially shifted based on the detrended observations of wake center positions. A schematic of the benchmark workflow First, we validate the predicted reduction of the mean velocity deficit due to wake meandering. The modified DWMM treating the wake as non-passive (i.e. using  $\bar{u}_a$  as the downstream advection velocity and  $S_{c_t} = 0.7$ ) is shown in Fig. ??. The mean velocity deficit in the MFOR was extrapolated with zeros outside the scanning cone of the rear-mounted Doppler LiDAR and only the part of the benchmark overlapping with the time delayed predictions of the DWMM is used. The effect of wake meandering on the mean velocity deficit and the turbulence intensity was then determined from the benchmark in the same way as for the observations (see Sect. 2.3.2 points eight and nine). The benchmark can be regarded as the best possible result that the DWMM could achieve.

Schematic of the benchmark used to validate the DWMM. The instantaneous wake center position (a,c) and the velocity deficit in the MFOR (b,c) are combined to create a benchmark wake (e) for comparison with the DWMM.

A comparison of the benchmark with the observations is shown in Fig. ??. The two main differences between the observations and the benchmark for the reduction of the mean velocity deficit (Fig. ??a, b) are (i) that for a 11a and compared to the observations in Fig. 11b. While both show that the recovery of the mean velocity deficit increases with the wake meandering strength, there is a main difference between the model and the observations: for a weak wake meandering strength (small values of  $\sigma(y_{wc})D^{-1}$ ) the observations scatter around zero, but the benchmark model has strictly positive values, and (ii) that the observations reach much larger values for strong wake meandering. This causes the benchmark to have model to have a smaller slope in a linear regression and a larger intercept compared to the observations. The negative values in the observations can be explained by the method of isolating the effect of wake meandering. Random fluctuations of the detected wake center position due to measurement errors or small-scale turbulence introduce erroneous, measurement resolution, and morphing of the wake introduce more variability into the MFOR than just the small-scale turbulence alone. If the wake meandering is weak, this erroneous variability in the MFOR can be of the same magnitude as the variability in the NFOR, thus leading to values scattering around zero. The larger values in the observations for strong wake meandering can be explained with a non-stationary flow that is attributed to the effect wake meandering in the observations, but is removed from the benchmark with the detrending of  $y_{wc}$ . If only a mean value is removed from  $y_{wc}$  instead of a linear trend, the differences in the slope of the linear regression between observation and benchmark reduces to 0.02.

For the Next, the model predictions of the added turbulence intensity due to wake meandering are validated. We observe that both the modified DWMM and the observations show an increase of the added turbulence intensity with the wake meandering strength (Fig. ??e, d), the slope of the linear regression has better agreement between the observations and the benchmark than for the 12a and Fig. 12b). Similar to the mean velocity deficit, while the offset for the intercept persists. The overall smaller differences between observations and benchmark can be explained by the lateral averaging of the quantification method, which averages strongly affected regions of the wake with more weakly affected regions further out (in contrast, the amplitude of the velocity deficit is quantified at the wake center only). Otherwise, in the previous paragraph, the same arguments as for the mean velocity deficit discussed in the previous paragraph apply.

**Figure 11.** The reduction of the mean velocity deficit as a function of the wake meandering strength at a downstream distance of  $x = 5D$ . Panel (a) shows predictions of the modified DWMM using  $\bar{u}_a$  as the downstream advection velocity with a turbulent Schmidt number of  $Sc_t = 0.7$  and panel (b) shows the observations. The error bars show the standard deviation of the measurement uncertainty propagated to the observed wake meandering strength or the predicted velocity deficit reduction, respectively. The 95% confidence bounds of the linear fit show the statistical uncertainty due to the scatter of the data points.

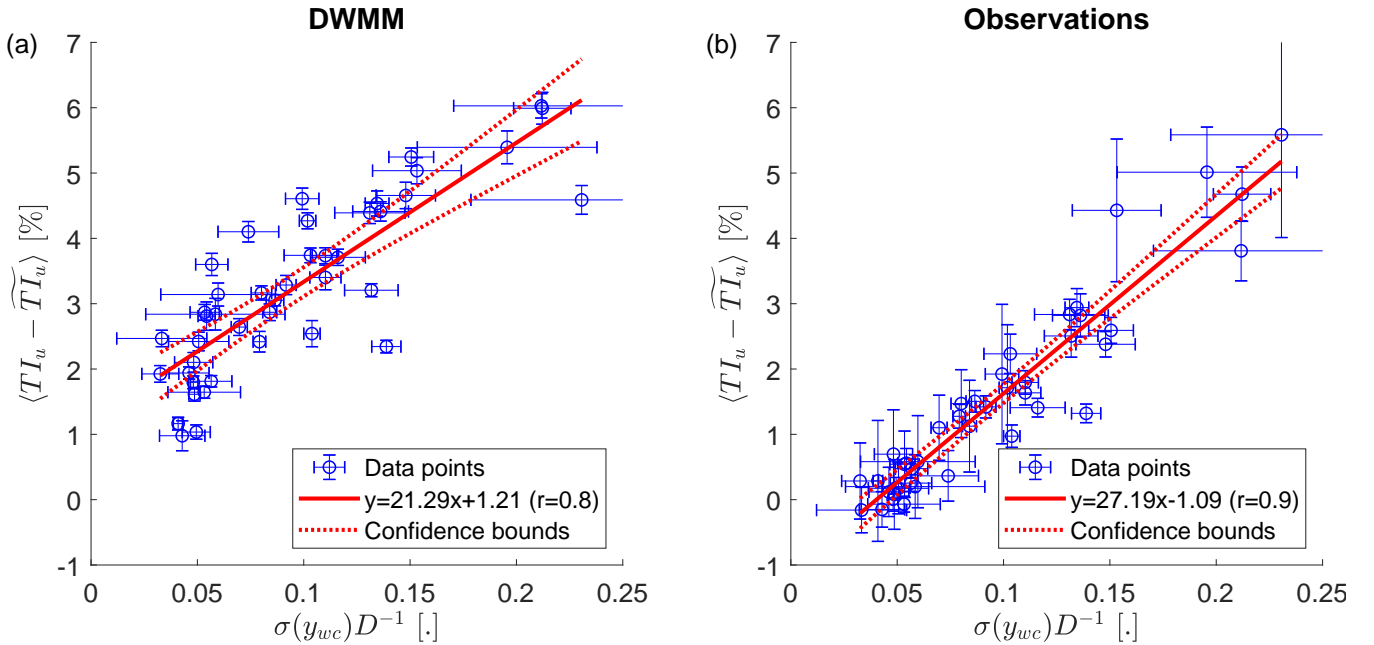

400 The observations (Fig. ??a, c), which include non-stationary effects, were plotted against the trend removed wake meandering strength. If the observations are plotted against the wake meandering strength including linear trends, the correlation coefficients increase to 0.8 and 0.9, respectively, and the linear regression assumes similar values as reported in Brugger et al. (2022) predictions of the DWMM are strictly positive for weak wake meandering, while the observations scatter around zero. This leads to a smaller slope and larger intercept for the model compared to the observations. The reason is that for weak wake meandering, the difference in turbulence intensity between the MFOR and the NFOR becomes very small and the aforementioned variance in the MFOR from other sources than small-scale turbulence affecting the observations lead to a scattering around zero.

### 3.2.2 Prediction Effect of modifications to the mean velocity deficit DWMM

First, we validated the predicted reduction of the mean velocity deficit by the DWMM. The

410 To investigate the effect of the proposed modification to the DWMM on the comparison with the observations, we compare three versions of the DWMM:

**Figure 12.** The ~~reduction of the mean velocity deficit (a, b), and the added turbulence intensity (c, d) due to wake meandering~~ as a function of the wake meandering strength at a downstream distance of  $x = 5D$ . ~~The left column Panel (a) shows predictions of the observations and modified DWMM using  $\bar{u}_a$  as the right column downstream advection velocity with a turbulent Schmidt number of  $Sc_t = 0.7$  and panel (b) shows the benchmark for observations.~~ The error bars show the ~~model validation standard deviation of the measurement uncertainty propagated to the observed wake meandering strength or the predictions of the added turbulence intensity, respectively.~~ The ~~red lines indicate a 95% confidence bounds of the linear fit show the statistical uncertainty due to the scatter of the data points.~~

1. ~~The original DWMM using the passive tracer assumption ( $\bar{u}_{hub}$  as the downstream advection velocity and  $Sc_t = 1.0$ ) produces comparable results to the benchmark (Fig. 11a).~~
2. ~~A semi-modified DWMM that only accounts for the slower downstream advection velocity without modifying the lateral transport ( $\bar{u}_a$  as the downstream advection velocity and  $Sc_t = 1.0$ ). The DWMM treating This is in line with recommendations in the literature for the application of the DWMM that suggest a downstream transport velocity slower than the mean wind speed, but do not mention further changes to the lateral and vertical transport equations of the DWMM (Bingöl et al., 2010; Brugger et al., 2022).~~
3. ~~The fully-modified DWMM as proposed here that treats the wake as non-passive (i.e. using  $\bar{u}_a$  as the downstream advection velocity and  $Sc_t = 0.7$ ) also produces comparable results to the benchmark (Fig. 11b). Both implementations of~~

~~Table 1 shows the root-mean-square error of a direct comparison between the observations and the three versions of the DWMM reproduce the trend of an decreasing mean velocity deficit with an increasing wake meandering strength. Only when including~~

dynamics into the validation as in Sect. 3.1, the benefit of non-passive implementation of the DWMM becomes apparent. The  
425 ~~good results of DWMM with the passive tracer assumption~~ DWMM. We observe from Table 1 that (i) the original DWMM and  
the fully-modified DWMM have similar errors to the observations, and that (ii) the semi-modified DWMM has a considerably  
larger error. This is the case for the effect of wake meandering on the mean velocity deficit as well as for the added turbulence  
intensity.

The similar results for the original DWMM and the fully-modified DWMM are explained by the temporally averaged valida-  
430 tion approach used here, where the errors of a too fast downstream transport and a too efficient lateral transport mostly cancel  
out, which might also explain why the issue was not noticed in previous studies. Overall, the good agreement to the benchmark  
shows that the DWMM is well parametrised and differences to the observations can be explained by factors that are not part  
of the framework validations. Only when including dynamics into the validation as in Sect. 3.1, the benefit of non-passive  
implementation of the DWMM becomes apparent.

435 Recommendations in the literature for the application of the DWMM suggest a downstream transport velocity slower than  
the mean wind speed, but do not mention further changes to the lateral and vertical transport equations of the DWMM  
(Bingöl et al., 2010; Brugger et al., 2022). However, treating the wake inconsistently in the DWMM by using  $\bar{u}_a$  (non-passive  
in the  $x$  direction) and  $Sc_t = 1.0$  (passive in the  $y$  and  $z$  direction) ~~The considerably larger error of the semi-modified DWMM~~  
440 ~~compared to the other two implementations is explained by the overestimation of the wake meandering strength observed in~~  
Sect. 3.1.1 that leads to an overestimation of its effect on the mean velocity deficit ~~reduction compared to the benchmark~~  
(Table 1, compare slopes of the three DWMMs). This result shows ~~and the turbulence intensity. This indicates~~ that only using  
a slower downstream transport velocity increases the errors compared to the other two implementations of the DWMM. This  
is in line with our finding from the first part of the results, that only using a slower downstream transport velocity in the ~~in~~  
the DWMM is not fully accounting for the non-passive nature of the wind turbine wake. Lastly, it should be mentioned that  
445 ~~the semi-modified DWMM is also treating the wake inconsistently by using  $\bar{u}_a$  (non-passive in the  $x$  direction) and  $Sc_t = 1.0$~~   
(passive in the  $y$  and  $z$  direction). Including the Schmidt number is required to accurately represent momentum transport in the  
wake.

The reduction of the mean velocity deficit as a function of the wake meandering strength at a downstream distance of  
 $x = 5D$ . Panel (a) shows predictions of the DWMM using  $\bar{u}_{t,ub}$  as the downstream advection velocity with a turbulent Schmidt  
450 number of  $Sc_t = 1.0$  and panel (b) shows the DWMM using  $\bar{u}_a$  with  $Sc_t = 0.7$ .

### 3.2.3 Prediction of the added turbulence intensity

Lastly, the model predictions of the turbulence intensity added by wake meandering are validated. The predictions of the  
DWMM have good agreement with the benchmark for both the passive and non-passive implementation (Fig. 12a and Fig. 12b).  
The reason why both advection velocities lead to good agreement with the benchmark is the same as for the reduction of the  
455 mean velocity deficit in the previous section. Overall, the impact of the downstream transport velocity and turbulent Schmidt  
number on the added turbulence intensity is smaller compared to the reduction of the mean velocity deficit shown in the

accurate downstream transport velocity had an error reduction for those statistics by ~~5% and 72%~~ and 1%, respectively (and better temporal agreement for the dynamics of wake meandering).

In future work, we propose a validation of our findings with a different experimental approach or through simulations to exclude site factors or methodological biases. It would also be interesting to investigate if the variability in the MFOR can be fully explained with the small-scale turbulence part of the DWMM. However, the latter requires wake measurements with a higher temporal and spatial resolution.

*Data availability.* The data is currently prepared to be published on Zenodo.

## Appendix A: Equations of the Bastankhah and Porté-Agel (2016) model

The normalized mean velocity deficit of the Bastankhah and Porté-Agel (2016) model for a wind turbine aligned with the mean wind direction is given by

$$\frac{\Delta \bar{u}}{\bar{u}_{hub}} = A(x) \exp\left(-\frac{1}{2} \frac{y^2 + x^2}{\sigma^2} - \frac{z^2}{\sigma^2}\right), \quad (\text{A1})$$

where  $A$  is the normalized mean velocity deficit at the wake center and  $\sigma$  is the wake width. The normalized mean velocity deficit at the wake center is given by

$$A(x) = \left(1 - \sqrt{1 - \frac{C_T}{8\sigma(x)^2/D^2}}\right) \quad (\text{A2})$$

with the thrust coefficient  $C_T$ . The thrust curve for this turbine model is not available to us and we will use an ensemble averaged thrust curve of several wind turbine models given there general similarity of  $C_T$  between different wind turbines (Fig. A1). The  $C_T$  is then chosen from the assumed thrust curve based on  $\bar{u}_{hub}$ . The wake width is given by

$$\sigma(x) = k^* \frac{(x - x_0)}{D} + \frac{1}{\sqrt{8}}, \quad (\text{A3})$$

where  $x_0$  is the near wake length and  $k^*$  is the wake growth rate. The growth rate is computed with  $k^* = 0.35TI_u$  assuming the linear relationship between  $k^*$  and the turbulence intensity found by Carbajo Fuertes et al. (2018). The near wake length  $x_0$  is given by

$$x_0 = \frac{1 + \sqrt{1 - C_T}}{\sqrt{2(\alpha^*TI_u + \beta^*(1 - \sqrt{1 - C_T}))}}, \quad (\text{A4})$$

where  $\alpha^* = 2.32$  and  $\beta^* = 0.154$ . For the computation of the advection velocity in Eq. (14) we use  $\bar{u}_{cen}(x) = \bar{u}_{hub}(1 - A(x))$  with  $A(x)$  given by Eq. A2 the assumption that  $A(x_0)$  is valid for  $x < x_0$ .

**Figure A1.** Thrust coefficient curves of six wind turbines from manufacturer data (first compiled by Abdulrahman, 2017) and the ensemble average, which is assumed as the  $C_T$  curve for wind turbine at the measurement site. Figure reused from Brugger et al. (2020) without changes under the Creative Commons Attribution 4.0 License (<https://creativecommons.org/licenses/by/4.0/>).

## 505 Appendix B: Tested hypotheses for the overestimation of the wake meandering strength

The following hypotheses for the overestimation of the wake meandering strength observed in Sect. 3.1.1 were tested:

- Temporal variations of the downstream advection velocity during a 14-minute period would lead to a reduced (increased) amplitude of the wake meandering during times with faster (slower) than average advection velocity. Utilizing the outside points of PPI of the wake scanning LiDAR to gain a time series of the wind speed, we found that the effect on the predicted wake center position is too small to explain the overestimation.
- A misalignment of the wind turbine could contaminate the lateral velocity measured by the front-mounted Doppler LiDAR with contributions from the longitudinal velocity. We used the yaw angle reported in the SCADA data, and the mean wake center position within the wake scanning LiDAR’s field of view to quantify the yaw misalignment of the wind turbine. The overestimation did not show any relationship to both neither in average nor trend.
- The overestimation persists if the mean instead of a linear trend is removed from  $v$  and  $y_{wc}$ . A decrease in magnitude in case of a removed linear trend is explained by removing the largest scales of turbulence.
- In case any remaining flow distortion of the wind turbine affecting  $v(t)$  went unnoticed, range gates at a greater distance than  $y = 117$  m were tested, but the overestimation persisted.
- We had the hypotheses that the onset of wake meandering is delayed due to a sheltering effect within the near wake until entrainment has reached the wake center. However, this assumption seems unrealistic based on the fact that the wake

scanning LiDAR shows wake meandering within the near wake. Testing hypotheses on the data led to a increased of the RMSE for  $xD^{-1} < 5$  due to an underestimation of the wake meandering there, and small decrease of the RMSE at greater  $x$ .
