Abstract. This paper investigates different actuator sector model implementation alternatives and how they compare to actuator line results. The velocity sampling method, tip correction, and time step are considered. A good agreement is seen between the line and sector model in the rotor plane and the wake flow. Using the sector model, it was possible to reduce the computational time by 75% compared to actuator line model as it is possible to run the simulation with a larger time step without compromising the accuracy considerably. The results suggest that the proposed velocity sampling method produces the closest results to the line model with different tip speed ratios. Moreover, the vortex-based tip correction applied to the sector model results in the lowest error values, among the considered methods, to correct the radial load distributions. Also, it is seen that reducing the time step compared to the one used for actuator disk/sector does not provide an advantage considering the increased computational time.

10 1 Introduction

The spatial and temporal scales present in simulating the flow field around wind turbines in atmospheric boundary layer (ABL) can vary from millimeters in the airfoil boundary layer to kilometers when studying wind farms. This puts the direct numerical simulation (DNS) of full Navier-Stokes equations outside of the reach of current high-performance computing (HPC) systems (Sørensen et al., 2015).

15 In light of this, conducting Large Eddy Simulations (LES) has become a common method to study different areas of interest such as the evaluation of power production and wake interactions under different operational conditions as it can resolve the wake dynamics for farm flows while keeping the computational cost affordable. This is significantly owed to the turbine models representing the complexities of blade-air interactions through simpler means. These models replace the blade geometry with a representative body force distribution in the computational domain. This can be done in a variety of ways.

20 For instance, in actuator disc models (ADM), the effect of the blades on the incoming wind is represented by body forces distributed asymmetrically over the swept area. After calculating the body forces, they are usually projected into the domain using a distribution such as a 3D Gaussian to avoid numerical instabilities caused by singular momentum sources. An unsteady-3D version of this model is proposed by Sørensen and Myken (1992) showing good agreement with experimental data in calculating the power values and capturing far wake properties. However, this model is equivalent to an infinitely bladed

25 turbine as it integrates the effect of the blades azimuthally. Therefore, it fails to predict the near wake flow field with high accuracy.

Another alternative is to represent each blade by a line on which the blade forces are calculated. This model was first introduced by Sørensen and Shen (2002) and is referred to as the actuator line model (ALM). ALM is more suitable for studying the near wake properties of the flow in detail and is able to reproduce structures such as tip vortices (Ivanell et al., 30 2010). However, this model is more computationally demanding partly due to an extra limitation on the simulation time step as a result of the high velocities experienced at the blade tip.

To overcome the additional computational demand of ALM, and the oversimplified representation of blades in ADM, a third alternative has been put forward. Storey et al. (2015) suggests using a sector to represent a blade and showed that this allows marching the solution with a time step similar to an ADM model while solving additional flow structures. The sector is the 35 area swept by a line within the time step used. In this study, this model is referred to as an actuator sector model (ASM). In a study by Nathan et al. (2015), it is shown how the resulted vortex system using this model is similar to that of an ALM. In addition, in separate studies by Krüger et al. (2022) and Vitsas and Meyers (2016), it is shown how ASM can be successfully coupled with an aeroelastic solver.

The mentioned rotor models use a blade-element approach where tabulated airfoil data and local flow field can be used to 40 calculate the radial force distributions along the rotor (Glauert, 1935). It is done by assuming radial and angular elements on the line, sector, or disc. Moreover, a correction for induction effects on the velocities is necessary due to various reasons. For instance, in ADM, a correction is needed to account for a finite number of blades (Shen et al., 2005). In comparison, smearing the body forces in ALM calls for another correction to account for the missing induction due to the viscous core behavior of the bound and trailing vortices as explained by (Meyer Forsting et al., 2019). However, in the case of ASM, it is not clear which 45 method would be able to correct the induced velocities at the rotor plane.

Despite the existing studies utilizing an ASM approach, the model implementation itself has not been scrutinized, although it may have significant effects on the results. For instance, Nathan et al. (2015) noticed a significant influence of the velocity sampling method on the torque values and calls for additional investigations. Therefore, in this study, different choices in the model implementation and their effect on the results are investigated. This includes the velocity sampling method, tip 50 correction, and time step size.

An overview of the actuator sector model used in this study is provided in chapter 2. In chapter 3, the numerical setup and different simulated cases are introduced. The results are presented and discussed in chapter 4. The findings of the study are summarized and concluded in chapter 5.

2 Model Description

55 In this section, an overview of the actuator sector model used in this study is presented, and the parameters studied in the parametric study are introduced.

One advantage of using an ASM approach is that the time step for the numerical simulation can be determined from the flow field's CFL condition permitting a larger time step compared to its ALM counterpart. This is achieved by using a sector instead of a line representation of the blades to project the body forces. The time step for ALM and ASM can be obtained from equation (1) and (2), respectively. In (1), the minimum cell length in the mesh is denoted by Δx , ω is the rotational speed, and R is the blade radius. The factor 0.75 is used as a safety factor for ALM while 0.5 is used for ASM to ensure the CFL condition is sustained. The safety factors are determined from preliminary simulations and are needed due to the use of flow properties at the inlet to calculate the time step.

$$\Delta t_{ALM} = 0.75 \cdot \left(\frac{\Delta x}{\omega \cdot R} \right) \quad (1)$$

$$\Delta t_{ASM} = \Delta t_{baseline} = 0.5 \cdot \left(\frac{\Delta x}{U_{incoming}} \right) \quad (2)$$

Compared to the actuator line method, each sector represents a blade and each sector is made of a number of lines starting from line 1 at the beginning of the sector and ending with line N_{sector} at the end of the sector. The sector angle θ_{sector} , the number of lines per sector N_{sector} , and the angle between the lines within a sector $\Delta\theta$, are determined using equations (3) to (5). A sector and the representation of its lines and line points are shown in Figure 1. The sector rotates clockwise with the turbine's rotational velocity and since the sector angle is determined from the time step and ω , the last line in the previous time step is the first line in the current time step.

$$\theta_{sector} = \Delta t \cdot \omega \quad (3)$$

$$N_{sector} = \left(\frac{\theta_{sector} \cdot R}{\Delta x} \right) + 1 \quad (4)$$

$$\Delta\theta = \theta_{sector} / (N_{sector} - 1) \quad (5)$$

Each line is composed of a number of equidistantly distributed points on which the forces are calculated. It is assumed that the contribution of the lines within the sector is equal. This means that the calculated force for each point is divided by the number of lines within the sector. In the first time step, the velocities are read from the computational domain for each line point. This is done by pre-calculating the velocity gradients on the entire disk area. Afterward, the velocity is sampled at the desired coordinate. Then, the forces are calculated based on the angle of attack and the tabulated airfoil data. Afterward, they are projected as body forces using the 3D Gaussian distribution in (6) where ϵ controls the smearing length and r_p is the distance from the control point to surrounding cell centers. In this study, the $\epsilon = 2\Delta x$ is used following the suggestion by

Figure 1. A sample sector with 5 lines and 8 line points

Troldborg (2009). Moreover, using a fixed ϵ value for all mesh resolutions would lead to losing some of the flow structures such as tip vortices for finer mesh resolutions and numerical instabilities for coarser mesh resolutions (Martinez et al., 2012).

$$\eta_\epsilon = \frac{1}{\epsilon^3 \cdot \pi^{3/2}} \exp\left(-\frac{r_p^2}{\epsilon^2}\right) \quad (6)$$

85 To update the rotor state when the blades rotate, two approaches are conceivable. In the first approach, after the body forces are projected into the domain, the velocity field is computed and read from the location of the sectors in the current step. Then, the sectors are rotated to their new location in the new time step and the blade forces are calculated and projected into the domain. This approach is referred to as the Old Position (OP). In contrast, it is possible to first rotate the sector, then, the velocities are read from the new position and blade forces are calculated and projected back to the domain. This is referred to as the New Position (NP) approach.

95 Both of these approaches are also conceivable for the actuator line method. The argument in favor of the OP approach is that the self-induction of the blade is zero. While in the NP, there is an induced velocity from the blade itself when it is first rotated forward into the next time step. As can be seen in Fig. 2, the power and thrust values have decreased with each refinement for the OP approach, as the forces become more concentrated due to the decreased value of ϵ which is proportionate to the cell side length. In contrast, using the NP approach, despite reducing the smearing length as the mesh is refined, the values of the thrust and power converge and are comparable to BEM results.

The choice of updating scheme is of greater importance for a sector compared to a line as its time step and spatial sweep are larger. Therefore, it is decided to present the results using both approaches wherever needed as there is no agreement in the literature regarding which approach is superior.

100 Regarding velocity sampling, in ALM, the velocities are sampled on the location of the blade points for each blade. However, in ASM, more methods are conceivable. In this study, three different choices are considered for the NP approach. In the first case, all velocities for all the lines are sampled at the beginning of the sector, i.e. at the first line. The second case samples

Figure 2. The comparison of power and thrust coefficients for OldPosition, NewPosition, and BEM results for different mesh refinements: (a)Power comparison, (b)Thrust comparison

the velocities for all the lines within the sector from the middle of the sector. If the number of lines is even, the average of velocities read on the two middle lines is used. The third case uses the local velocity at the location of each line point. For the OP approach, 7 cases are considered. It includes sampling at 0.5, 0.6, 0.7, 0.8, 0.9, and 1 of the sector for all lines as well as the local velocity sampling at the location of each line. For instance, 0.5 means the velocities are sampled from the azimuth going through the mid-sector and 1 represents the case where the velocities are sampled from the azimuth at the end of the sector.

Another detail of ASM to investigate is the choice of tip correction. On one hand, ADM requires a tip correction as proposed by Shen et al. (2005) to take into account the effect of using a finite number of blades. However, the correction requires a fine-tuning of the coefficients for different rotors. Therefore, another commonly used tip correction method for ADM is the Glauert (1935) correction. Nonetheless, it does not produce accurate results as originally intended for BEM calculations where the relation between the velocity and forces is not exact.

Furthermore, distributing the forces in ALM using the smearing function leads to an induced velocity profile similar to a viscous core as shown by Dağ and Sørensen (2020) and Meyer Forsting et al. (2019). Therefore, the missing part of the induction calls for a correction. To account for this, a vortex-based correction is suggested and implemented by Meyer Forsting et al. (2020). However, there is no consensus on which tip correction would be required for ASM. For this reason, three aforementioned tip corrections are considered to investigate which one would result in satisfactory results for an actuator

Figure 3. The illustration of the computational domain: Left: front-view slice at the rotor plane, Right: side-view at the mid plane

Table 1. The sector properties for different mesh resolutions for TSR=7.55

No. of cells along the rotor diameter	θ_{sector}	N_{sector}
16	6.75°	5
32	13.50°	5
64	27.00°	5

sector. Although it is conceivable that a tip correction method could be devised for the actuator sector model, this paper aims to determine if currently available methods can correct the load distributions adequately.

120 It is mentioned earlier that ASM allows for increasing the time step thereby reducing the calculation time. In order to evaluate the trade-off between the time step size and model accuracy compared to ALM, two smaller time steps than the baseline time step that is calculated from (2) are considered. This includes $\frac{\Delta t_{baseline}}{2}$ and Δt_{ALM} .

3 Numerical Setup

In this section, the numerical setup used in this study is presented. As explained in section 2, three main parameters in model implementation are investigated. This includes the velocity sampling method, tip correction, and the time step. Moreover, three mesh sizes are run for each case of sampling method and tip correction to investigate the effect of the mesh size.

The model is implemented in OpenFOAM by modifying the actuator line implementation found in Simulator fOr Wind Farm Applications (SOWFA) library (Churchfield et al., 2012)(Weller et al., 1998). The boundary conditions used are uniform inflow for the inlet, no shear for the outlet, and slip condition for the lateral, upper, and lower sides. The data from the NREL 130 5MW reference turbine is used for the simulations (Jonkman et al., 2009). The inflow velocity is set to 8 ms^{-1} and the tip speed ratio (TSR) is 7.55.

The used domain is $10D \times 10D \times 20D$ and the turbine is placed 4 diameters downstream of the inlet to minimize the effects from the boundaries. There are two cylindrical refinement areas in the mesh where one is located inside the other one. This way, the cell sides are half and one-fourth of the outermost cell sides for the outer and inner refinement areas, respectively. 135 Therefore, there are 16, 32, and 64 cells per rotor diameter for the coarse to fine mesh, respectively. The computational domain is illustrated in Fig. 3. The sector properties for each of the mesh resolutions used are summarized in Table 1.

Figure 4. Body force distribution in the rotor plane for ALM, ASM, and ADM, respectively from left to right

The sub-grid scale modeling is done using the modified Smagorinsky model of Mason and Thomson (1992) with model constants of $C_e = 0.93$ and $C_k = 0.0673$. Each case is run for 600 seconds as it is seen the thrust and power values do not change considerably after about 450 seconds which corresponds to flow passing through the entire domain about 3 times. Regarding the finite volume schemes, a backward time scheme is used. The interpolation scheme for velocity divergence is local blended linear upwind. This scheme uses 90% linear and 10% upwind for cell face areas equal to or smaller than $(D/32)^2$ while 80% linear and 20% upwind for larger ones. A PGC solver is used for solving the linearized equations with a maximum tolerance of 10^{-6} . The rest of the parameters are left unchanged as the ones used in the standard ALM settings in SOWFA.

4 Result and Discussion

In this section, the results obtained from the parametric study on ASM are presented and discussed. In addition, the results from ADM, ALM, and BEM are provided occasionally to observe how these models compare to the results of ASM. First, a comparison of different models regarding the resulting solution in the rotor plane is presented. Second, the results from the investigation of different sampling methods are presented for both OP and NP approaches. This is then supplemented with a sensitivity analysis on the effect of TSR value on the choice of the preferred sampling method. It is followed by evaluating the mentioned tip/smearing corrections. Next, it is tested whether using a smaller time step for ASM compared to its baseline provides an advantage. In the end, the wake profiles and near wake contours of ASM, ALM, and ADM are compared and the computational saving associated with ASM is quantified.

4.1 Rotor Plane Solution

Here, the resulting solutions from ASM, ALM, and ADM in the rotor plane are presented. It includes the magnitude of body force, vorticity, and velocity. For the sake of conciseness, only the results from the OP approach are presented. The obtained results from the NP approach are similar, although they differ in values. The used mesh has 64 cells along the rotor diameter.

Starting with the body force, as can be seen in Fig. 4, ASM projects a similar distribution as ALM with a distinguished 3-bladed representation of the rotor. However, the forces are more concentrated in ALM as the entirety of the calculated blade

Figure 5. Velocity magnitude distribution in the rotor plane for ALM, ASM, and ADM, respectively from left to right

Figure 6. Vorticity magnitude distribution in the rotor plane for ALM, ASM, and ADM, respectively from left to right

forces is projected from one line while for ASM the forces are split between 5 lines. Looking at the azimuthal distribution of
160 the body forces in the rotor plane as shown in Fig. 7 at 0.8 of the rotor radius, it can be seen how the body force projection
of ALM and ASM in the rotor plane differs. ASM has projected the body force in a wider length leading to a lower peak.
Nonetheless, the shape of the distributions and the integral of the body forces are comparable.

Regarding the velocity and vorticity magnitude distribution, as seen in Fig. 5 and Fig. 6, ASM has been able to create a
similar solution in the rotor plane compared to ALM. The lower extremes seen in ASM compared to ALM are due to the wider
165 body force projection. Moreover, since the blade forces are projected normal to the rotor plane with the same varying ϵ which is
dependent on Δx similar to the one used in ALM, the vortex structures are not diffused in the near wake due to the high values
of ϵ as shown by Martinez et al. (2012). This explains how ASM is able to capture the flow structures in the near wake with an
accuracy similar to ALM. These observations provide an indication that using a sector approach, it is possible to recover the
ALM solution to a great extent.

170 4.2 Velocity Sampling Method

Here, the results from different cases mentioned in section 2 for OP and NP approaches are presented. The cases are run for 3
mesh resolutions with 16, 32, and 64 cells along the diameter, respectively. All cases use the vortex-based smearing correction

Figure 7. Azimuthal distribution of body force for ALM and ASMs with OP approach for the fine mesh with 64 cells along the rotor diameter.

Figure 8. Relative errors of power and thrust values of different sampling methods compared to their ALM counterpart of the same mesh resolution with old position updating scheme: (a)Power relative error, (b)Thrust relative error

by Meyer Forsting et al. (2020). The ALM results of the same mesh resolution and updating approach are used for investigating which sampling method matches its ALM counterpart to a greater extent.

175 4.2.1 Old Position Approach

The relative error of power and thrust values is calculated for cases of different mesh resolutions and sampling methods with respect to their ALM counterpart. As can be seen in Fig. 8, the best match with ALM results is achieved for the sampling method where the velocities are sampled at 0.7 of the sector. The relative error compared to ALM is around -2% and -0.5% for power and thrust, respectively. According to Fig. 9, the power and thrust values have increased with the sampling location moving from 0.5 or mid-section to 1 or the end of the sector. Using the local sampling method has led to values comparable with sampling from the midsection.

180

Figure 9. Power and Thrust values for ASM of different sampling methods along with their ALM counterpart for different mesh resolutions with old position updating scheme: (a)Power, (b)Thrust

One of the differences between ALM and ASM is the induction caused on one line by other lines within the sector. However, it is conceivable that there should exist an azimuth within the sector where the cumulative induction from all lines thereby the axial velocity resembles the one obtained in ALM.

185 Based on our investigation, at 0.7 the axial velocity matches best with the one from ALM for OP as shown in Fig. 10. Moreover, it is seen how the axial velocity changes throughout the sector on each line. It is noteworthy to mention that although the line forces are equal in each time step for a non-locally sampled model, it does not lead to a symmetric axial velocity azimuthal distribution in the midpoint. This is further illustrated in Fig. 11. In addition, the axial velocity change between one line to the next increases by moving farther from the sector beginning thus a higher force and induction. This shows why a
 190 locally sampled model such as the one used by Nathan et al. (2015) or from midpoint as Storey et al. (2015) proposed, do not produce the closest results to ALM.

On another note, by recovering the force distribution similar to ALM, by means of sampling from a certain azimuthal position, a similar solution to ALM (in the flow field) is obtained. This could imply that the effect of the different projections of the forces is not as significant compared to the blade force distribution. Therefore, it is conceivable that using an analytical
 195 model such as the one described in (Sørensen and Andersen, 2020) would be also practical in ASM when required data for blade element calculations is not unavailable. However, the results will be only as accurate as the model used to calculate the blade forces.

4.2.2 New Position Approach

The power and thrust values for the ASM cases considered are presented in Fig. 13 along with their ALM counterpart of the same updating approach for different mesh resolutions. The converging behavior seen in Figure 2 for ALM with NP is only
 200 seen for the case where the velocities are sampled at the beginning of the sector. For this case, as can be seen in Fig. 12, the relative error remains below 3% and 2% for power and thrust, respectively. It is noteworthy that this case is equivalent to the case for OP where velocities were sampled at the end of the sector.

Figure 10. Radial distribution of axial velocity on ALM, ASM-local lines, and ASM-0.7 with OP approach for the fine mesh with 64 cells along the rotor diameter.

Figure 11. Azimuthal distribution of body force and axial velocity for ASM-0.7 with OP approach for the fine mesh with 64 cells along the rotor diameter

Similar to 4.2.1, the results of sampling locally or from the mid-section are somewhat alike. Moreover, moving the sampling location away from the sector beginning has increased the power and thrust values. The error values increase sharply with increasing the mesh resolution for the 0.5 and local sampling methods. This shows how relying solely on the results from a relatively coarse mesh can be misleading for tuning this model's parameter. For these cases, where the sampling is not done from the sector beginning, the results of ASM with NP approach do not match its ALM counterpart as the velocities are sampled from an azimuth where the blade has not physically reached yet.

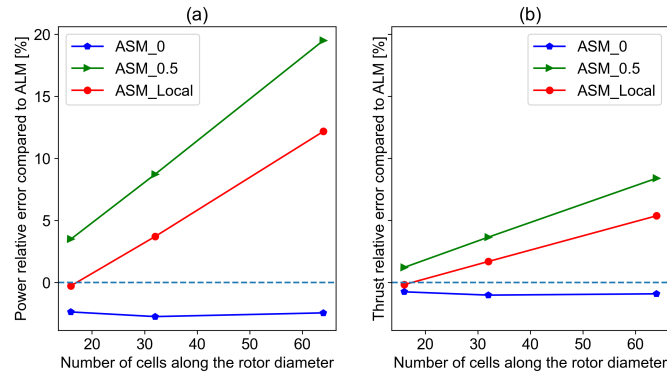

Figure 12. Relative errors of power and thrust values of different sampling methods compared to their ALM counterpart of the same mesh resolution with new position updating scheme: (a)Power relative error, (b)Thrust relative error

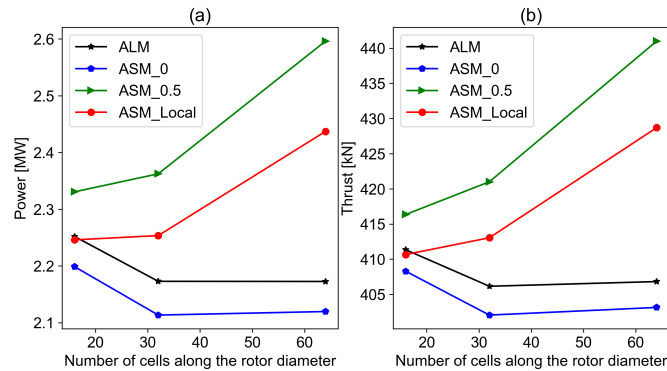

Figure 13. Power and Thrust values for ASM of different sampling methods along with their ALM counterpart for different mesh resolutions with new position updating scheme: (a)Power, (b)Thrust

210 4.2.3 Sampling Location Sensitivity to TSR

To ensure that the results obtained from subsection 4.2.1 and subsection 4.2.2 can be generalized to other tip speed ratios relevant to modern wind turbines, additional simulations with two TSR values of 6 and 9 are performed for both ALM and ASM with mesh resolutions of 16, 32, and 64 cells along the rotor diameter while other parameters are kept unchanged. Only the results from OP updating scheme are presented here. The relative error for power is calculated for the ASM-0.7 case compared to its ALM counterpart of the same TSR and mesh resolution corresponding to the lowest error values for the original TSR of 7.55. As shown in Fig. 14, the error values increase with larger TSR values and vice versa. This is expected as lowering TSR reduces the sector angle, bringing the sector closer to a line. Also, this will further reduce the difference between the time steps used for the line and sector models. Moreover, it is noteworthy to mention that the diverging behavior observed

215

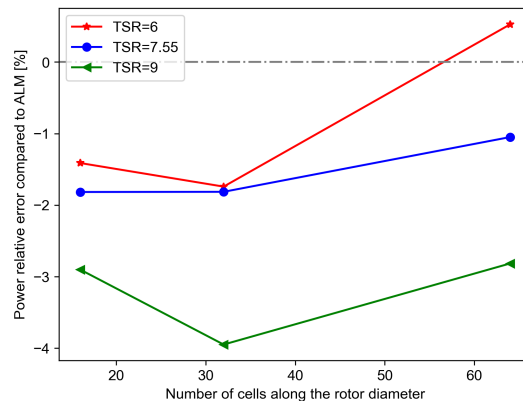

Figure 14. Relative error of power value for different TSRs compared to their ALM counterpart of the same mesh resolution

in Fig. 8 for most cases, is not present for the sampling location of 70%. Therefore, the proposed sampling method is capable
220 of performing well in a range of relevant TSRs.

4.3 Tip/Smearing Correction Method

As explained in section 2, three tip/smearing corrections methods have been put to test to investigate which one will suit an
ASM model to a greater extent. It includes the corrections by Glauert (1935), Shen et al. (2005), and Meyer Forsting et al.
(2020). The sampling method from 0.7 and the beginning (0) of the sector are considered for OP and NP schemes, respectively.
225 The investigated mesh has 64 cells along the rotor diameter. The radial distribution of axial and tangential forces are compared
to their ALM counterpart of the same mesh resolution and updating scheme. In addition, the load distributions from BEM
method using a Prandtl tip correction are presented to complement the comparisons (Prandtl and Betz, 2010). This will provide
an unbiased measure since ALM is also using the vortex-based correction.

For the NP scheme, as can be seen in Fig. 15 and Fig. 16, the vortex-based smearing correction has resulted in the closest
230 values to both ALM and BEM outputs with great accuracy. It is not surprising that the correction intended for ALM performs
better in comparison to Glauert (1935) or Shen et al. (2005) tip corrections intended for BEM calculation and ADM, respec-
tively as the sector is more similar to a line than a disc. The mean relative error compared to ALM for the vortex-based case is
1.35% and 2.80% for the axial and tangential force, respectively. Using Glauert (1935) correction has led to an underprediction
of the forces near the blade tip while using Shen et al. (2005) correction has overpredicted the forces in the tip region. Taking
235 a closer look at the results for the vortex-based correction, it can be seen that although there is an error compared to BEM, the
force distribution follows the same trend in the tip region.

The same trend and findings are true for the OP scheme showing the superiority of the vortex-based smearing correction
among the investigated methods and its ability to correct the induced velocities in the rotor plane for an actuator sector. The
mean relative errors for radial distribution of axial and tangential forces are 0.57% and 1.20% and the results are presented in
240 Fig. 17 and Fig. 18.

Figure 15. Tangential and axial force per unit length comparison with ALM and BEM results with new position updating scheme: (a)Tangential force per unit length, (b)Thrust per unit length

Although the results are satisfactory and comparable to ALM with high accuracy, the larger time step and wider projection of forces in ASM call for an investigation to address and identify the potential effects of these differences to develop a vortex-based smearing correction tailored for ASM applications. Meanwhile, the correction proposed by Meyer Forsting et al. (2020) can be used with enough confidence.

245 4.4 Time-step Size

In this part, the effect of reducing the ASM time step toward its ALM equivalent is investigated to find out if using a smaller time step -thereby a smaller sector angle- can improve the model's accuracy. Although this would remove the model's advantage of reducing the computational power, it provides useful insight into how the model is dependent on the choice of the time step. Two smaller time steps are considered. The smallest time step is equal to ΔT_{ALM} and the other one is half of the ASM baseline time step. The highest resolution mesh with 64 cells along the rotor diameter is used. For each updating scheme, two sampling methods are considered. It includes 0.7 and local for OP and 0 and local for NP. As a reminder, 0.7 and 0 correspond to sampling the velocity from the 70% and beginning of the sector for all the lines within the sector, respectively and local sampling refers to reading the velocity separately for each line based on their location in the sector.

250

Figure 16. Tangential and axial force relative error compared to ALM with new position updating scheme: (a)Tangential force relative error, (b)Axial force relative error

The power and thrust values for ASMs with different sampling methods and updating schemes are presented in Fig. 19. Moreover, the ALM and BEM results are also provided. As can be seen, reducing the time step and thereby the sector angle has reduced the thrust and power values for the cases with the NP updating scheme. In contrast, the power and thrust values have increased for the cases with the OP updating scheme. For both the OP-0.7 and NP-0 cases that previously showed the best match with their ALM counterparts, the model's accuracy compared to ALM has declined while the accuracy has increased compared to BEM results. Nevertheless, the change in the values are not significant and are comparable with both ALM and BEM results. For the cases with the local sampling method, there is a great change in the power and thrust values. Reducing the time step has shown a great improvement for both local cases. As can be seen in Fig. 20, running a locally sampled ASM model with the same time step as ALM has almost resulted in the same values since the only difference is that ASM uses two lines compared to ALM with one line.

Although reducing the time step takes away the advantage of ASM being faster, it shows how these two models relate to each other. Also, the increase in the error value for the previously tuned sampling location of 0.7 and 0 for OP and NP, can be an indication of how the sampling location is related to the sector angle, number of lines, and their effect on each other through induction. Nonetheless, as the error for thrust and power remained within an acceptable range, the proposed sampling locations

Figure 17. Tangential and axial force per unit length comparison with ALM and BEM results with old position updating scheme: (a)Tangential force per unit length, (b)Thrust per unit length

may be used in good confidence. Quantifying the dependence of the sampling location on the sector angle shall be investigated in future works.

270 4.5 Near Wake Analysis

In this part, the near wake profile resulting from ASM, ALM, and ADM are presented and compared with each other to investigate to what extent ASM is able to capture the flow structures in the near wake. Also, TKE profiles resulting from each of these models are compared in the streamwise direction. To be concise only the results from the OP approach are presented.

As can be seen in Fig. 21, the helical vortex system captured in ALM is recovered to a great extent by using ASM. In comparison, ADM does not capture any tip vortices and releases a vortex sheet downstream. In spite of capturing the tip vortices in ASM, the maximum value for vorticity is lower compared to ALM as the body forces are less concentrated. The maximum value of vorticity in the near wake of ALM is 0.87 1/s compared to 0.82 and 0.56 for ASM and ADM, respectively. Looking at the TKE profile of the models for the last 150 seconds of the simulation along the streamwise direction, as seen in Fig. 22, TKE profiles of ALM and ASM at the rotor agree with each other and are distinct from ADM. However, further

Figure 18. Tangential and axial force relative error compared to ALM with old position updating scheme: (a)Tangential force relative error, (b)Axial force relative error

280 downstream, the profiles become similar. For a courser mesh where the tip vortices for ALM and ASM have not formed, TKE values at the rotor are lower than those seen in Fig. 22. Comparing Fig. 22 and Fig. 23, it can be seen that even in the downstream of the rotor, ASM and ALM are more in agreement compared to ADM. However, they become more similar as moving downstream. This is in line with the results obtained by Troldborg et al. (2012). Moreover, using a finer mesh has reduced the difference between the models downstream.

285 4.6 Computational Efficiency

Here, a comparison is made between the computational time required for running a similar case with ALM and ASM. Therefore, the mesh and the total simulated time is the same for all cases. Both ALM and ASM models use the vortex-based smearing correction. All models have the NP updating scheme. The ASM model samples the velocities from the sector's first line while sampling for ALM is done locally. The time step used for each of the cases is tabulated in Table 2. Using ASM it has been possible to reduce the computational demand to almost one-fourth or by three-quarters of what is needed for ALM, rendering it to be a faster alternative.

290

Figure 19. The power and thrust values for different ASM/ALM of different sampling methods and updating schemes, the dashed line represents the BEM results: (a)Power vs ΔT , (b)Thrust vs ΔT

Table 2. The time step used for each model

Model	ΔT [s]
ASM	0.123
ALM	0.024

295 Although the time step used for ASM is 5.125 times larger than the one used for ALM, the CPU time needed for ASM is not as short. This is partly due to the higher number of lines or sub-time steps required in ASM -depending on how the algorithm is implemented- and the associated calculations and tasks. Additionally, this could be due to the shortcomings of the parallelization algorithm used in the flow solver, since the computational time required to solve the flow field is higher compared to the number of calculations needed to compute the body forces (about 1 percent of computations). A further investigation showed that using the sub-time-steps approach can reduce the computational cost almost proportionally to the time-step size.

Figure 20. The relative error for power and thrust values compared to ALM of the same updating scheme for different ASMs of different sampling methods: (a)The relative error for power vs ΔT , (b)The relative error for thrust vs ΔT

5 Conclusions

300 The purpose of the current study was to investigate the effects of different available options regarding the actuator sector model implementation in order to determine the combination leading to the closest results to ALM while improving the computational speed. It includes the velocity sampling method, tip/smearing correction, and the choice of the time step. To do so, the rotor plane and near wake solutions resulting from ASM are compared to ALM, ADM, and BEM results where deemed suitable.

Two updating schemes for the rotor state are studied. The updating scheme determines whether the velocities are sampled
305 before or after the blade rotation to calculate the body forces. Old position (OP) refers to the approach where the velocity sampling for the current time step is done before rotating the blades into their position in the current time step whereas new position (NP) refers to sampling velocities for the current time step after the blades are rotated. The study has identified that the velocity sampling location at 70% of the sector with OP updating scheme produces the closest results to ALM. The relative errors compared to ALM for power and thrust values are around -2% and -0.5%, respectively. In comparison, when NP updating
310 scheme is used, sampling the velocity from the sector's beginning results in a solution closest to its ALM counterpart. However, as this is equivalent to sampling velocities from the sector's last line with OP approach and a considerable overestimation of the forces was seen for other sampling choices with NP approach, its application is ruled out. The effect of tip speed ratio (TSR) on the choice of sampling method showed that increasing TSR increases the error values compared to ALM. However, using the recommended approach to sample the velocities keeps the errors within an acceptable range.

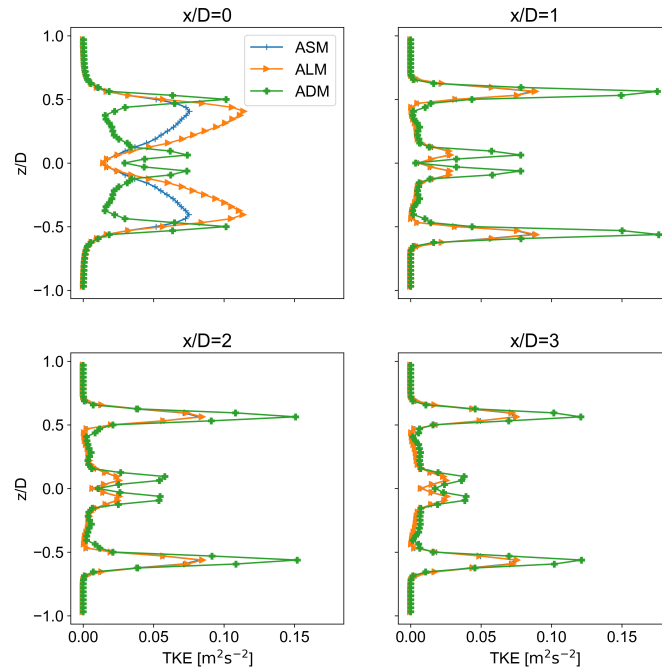

Figure 23. TKE profile along the stream-wise direction for ALM, ASM, ADM, moderate mesh with 32 cells along the rotor diameter.

315 The study has confirmed that using the vortex-based smearing correction for ASM will provide the closest load distributions on the turbine blades compared to its ALM counterpart with great accuracy yielding a mean relative error of 0.57% and 1.2% compared to ALM for radial and tangential load distributions, respectively. This is considerably lower than the other alternatives, especially near the hub and tip regions. Regarding the near wake, TKE profiles of the ASM and ALM showed great agreement with each other and were different than ADM. The difference is at its peak at the rotor. Although the difference
320 reduces farther downstream, ASM and ALM were closer to each other. The computational saving of ASM compared to ALM is quantified to be around 75%. Reducing the time step made no significant difference to accuracy considering the reduced speed.

These findings suggest that ASM can potentially replace the commonly used line and disk actuator models for wind power applications as it offers a compromise between computational saving and accuracy compared to ALM as it can capture the
325 near wake dynamics to a better extent than ADM. The present study appears to be the first to investigate the effect of different choices regarding the ASM implementation. This contributes to the adoption of this model by academia as an alternative in the field. However, there are limitations to this study that need to be addressed in future works. The study was limited by the absence of turbulent, yawed, and sheared inflow. Therefore, investigating these cases would be necessary to establish the model's reliability in more realistic conditions.

330 *Code and data availability.* The model implementation code and the simulation data files for different cases resulting from the parametric study can be provided upon request.

Author contributions. M. M. Mohammadi and S. Ivanell designed the methodology and M. M. Mohammadi carried them out. M. M. Mohammadi developed the model code and performed the simulations. G. P. Navarro Diaz contributed to the simulation setup. M. M. Mohammadi prepared the manuscript. S. Ivanell and H. Olivares-Espinosa provided feedback on it.

335 *Competing interests.* The authors declare that they have no conflict of interest.

Acknowledgements. This work has been funded by Swedish Energy Agency. The simulations were run using resources provided by Swedish National Infrastructure for Computing (SNIC). Henry Korb, Henrik Asmuth, and Alexander Meyer Forsting provided feedback on different parts of this study.
