Abstract. It is well-known that wakes caused by the wind turbines within a wind farm negatively impact the power generation and mechanical load of downstream turbines. This is already partially considered in the farm layout. Nevertheless, the strong interactions between individual turbines provide further opportunities to mitigate adverse effects during operation, e.g., by repeatedly adjusting axial induction or yaw angles to current offsets to wind conditions. We propose a mathematical approaching, that covers the farm by patterns based on a smaller, precomputable so-called upstream section, in the form of integer programming for faster globally optimal yaw control (under some mild assumptions like discretized yaw offsets, chosen size of upstream section, and homogeneous layout structure). While we prove the wind farm yaw problem to be strongly  $\mathcal{NP}$ -hard in general, we demonstrate through numerical experiments that our method is efficient in practice and enables optimal yaw control under real-world requirements on control update periods. In particular, the approach remains efficient if turbines are deactivated and scales reasonably well with increasing farm width.

Keywords. Wind farm, optimization, yaw-based control, integer programming.

#### 1 Introduction

Wind turbines are considered one of the most important electric power plants of the future energy grid, since they can generate electricity cheaply and with low green house greenhouse gas emissions, see, e.g., Kost et al. (2018). Naturally, they are placed in wind farms at locations with desirable year-round wind conditions (onshore on- or offshore), to ensure a high energy yield in general. To further increase efficiency, increase efficiency during operation, one exerts a turbines are control controlled on a turbine, i.e., periodically adjusts parts of it are periodically adjusted (e.g., nacelle orientation towards direction relative to the wind, i.e., the so-called yaw-based control, generator torque or blade pitch angles) to positions that are most beneficial the most beneficial positions with respect to the current wind speed and direction. The conventional control consists of a greedy strategy in which a turbine maximizes its own power output under certain durability considerations, see, e.g., Hau (2013). In a farm, such greedy control can lead to suboptimal total power output of the farm as a whole (as well as to increased maintenance requirements effort for the turbines) because as the turbines influence one another due to their spatial proximity: Each each turbine causes a wake, which is characterized by decreased wind speed and increased turbulence, and naturally impacts downstream turbines regarding both power output and mechanical load (wear and tear). The local control of a (single) turbine affects the length and the spatial distribution of its wake. This opens the possibility for a global control that incorporates

Figure 1. Simulation of the local wind speed (in m s<sup>-1</sup>) with 6 turbines (of type NREL 5-MW) arranged in a  $2 \times 3$  grid layout; axes give on-ground distances (in m). The wind blows from the left side west to east with a speed of  $11 \,\mathrm{m\,s^{-1}}$  with a turbulence intensity of 6%. It is decreased by the turbines and, additionally, the wakes are deflected by the turbines in the first and second column because of their yaw angle offset of  $15^{\circ}$ . (The downstream-most turbines have a yaw angle offset of  $0^{\circ}$ .) This figure was produced using the software WinFaST, see Sect. 3.1 for a description.

turbine interactions within the entire wind farm. In general, such a wind farm flow control is state of the art, see, e.g., Meyers et al. (2022) for an overview. In this paper we will. We focus on the optimization of the nacelle orientation towards the wind, i.e., the so-called yaw-based control, yaw offsets, which deflect and deform wakes, see, e.g., Annoni et al. (2018), as in Fig. 1, to maximize the total power of the wind farmfarm's total power, which is the most important a primary objective, see, e.g., van Wingerden et al. (2020). The effect of yaw angles on wakes is shown in Fig. 1.

In the following, we discuss the wake models, farm layouts and operations to motivate the wind farm yaw problem and paraphrase our approach along with contributions and limitations; an outline of the remaining paper concludes this introduction.

The remaining paper is structured as follows: in Sect. 2, we formulate the *wind farm yaw problem* (WFYP) mathematically, we motivate and develop our *covering approach* (CA) and the corresponding *integer program* (IP). The details on precomputations, i.e., on the simulation and the resulting performance indicators are described in Sect. 3. We explain and discuss the results of our computational experiments in Sect. 4 and finally, conclude in Sect. 5. The theoretical complexity of the WFYP is examined in Appendix A. We abbreviate farm for wind farm, turbine or WT for wind turbine, and TI for turbulence intensity.

#### 1.1 Related work

Wake models in the literature are often parameterized to NREL 5-MW turbines, see Jonkman et al. (2009) for details, in usual atmospheric conditions for onshore wind farms, see Sect. 3.1 for details. The following brief survey refers to this turbine type; for a detailed overview of the complex topic of wind farm flow control, we refer to, e.g., Meyers et al. (2022). High-fidelity simulations of wind farms in 3D like the *Simulator for Wind Farm Application* (SOWFA), see Churchfield et al. (2012a, b); Fleming et al. (2013), are time-consuming and, hence, impractical for use in control. An overview of the most important control-oriented models in 2D is given in (Annoni et al., 2018, Sect. 2.1): first, the Jensen model, see Jensen (1983); Katic et al. (1987) (also for a further developed model); second, the multi-zone model FLORIS, see Gebraad et al. (2014), which has the dynamic extension FLORIDyn, see Gebraad and van Wingerden (2014); and third, the Gaussian model, see, e.g., Bastankhah and Porté-Agel (2016). These models are continuously being developed further. In the present work, we use a simulation software which utilizes a wake model based on FLORIDyn, cf. Sect. 3. If the focus were only on power, i.e., disregarding loads, a static model would suffice. In that case, the state-of-the-art State-of-the-art static wake models are the Gauss-Curl-Hybrid model, which incorporates secondary effects of wake steering, see King et al. (2021), is recommended, or and the cumulative-curl wake model if there are more than a few wake interactions, see Bay et al. (2023). Both are implemented in the rapidly evolving software FLORIS (not to be confused with the original model), incorporating several steady-state control-oriented wake models, see NREL (2024).

These control-oriented wake models have limitations: For for a comparison between FLORIDyn and SOWFA we refer to Gebraad and van Wingerden (2014); in particular, Fig. 5 there illustrates locally strong speed fluctuations in the wind field. In general, wind turbulence depends on a number of meteorological and topographical factors, see (Hau, 2013, Sect. 13.4). However, the power output essentially depends on long-term fluctuations whereas loads are caused by short-term fluctuations, see Hau (2013). Furthermore, in the case of specific atmospheric conditions, real-world wakes of offshore wind farms can have a length of 45 km, see Platis et al. (2018), which cannot be predicted by control-oriented models. In . In any case, the mathematical approach we will propose utilizes a superordinate model in which the underlying wake model is , in principle, interchangeable.

A profitable wind farm needs a suitable location and careful planning of turbine numbers and placement. *Wind farm layout optimization* relies on yearly wind frequency data (wind direction and speed). It has been known for decades that it is useful to avoid wake-induced yield reductions of downstream turbines by setting them far enough apart, see, e.g., Katic et al. (1987). While first attempts to account for such effects merely simulated the annual average output of a specific farm layout, see Katic et al. (1987), in recent years, the layout problem was optimized globally by mixed-integer and constraint programming, see, e.g., Zhang et al. (2014); Fischetti (2017, 2021). In addition to the annual energy output, noise propagation is a concern in case of onshore farms that can also be considered, see Zhang et al. (2014). For offshore farms, aspects of cable routing and jacket foundations are worth taking into account, see Fischetti (2017); Fischetti and Pisinger (2019).

For a given wind farm (i.e., a fixed layout), it is conventional to run greedy control for each individual turbine, see, e.g., Hau (2013). As mentioned earlier, adopting a global control for the whole farm instead of local control of separate turbines can potentially improve the overall power output and relieve physical strain on the turbines. In general, there are two common global control concepts, cf., e.g., Gebraad et al. (2015); Annoni et al. (2016); Meyers et al. (2022): axial induction-based control (of generator torque and/or the collective blade pitch angle) and yaw-based control (of the turbine yaw anglesoffsets), which is also known as wake steering control, see, e.g., Howland et al. (2019). Both control concepts effectively reduce power generation of upstream turbines by adjusting torque/pitch or yaw, respectively, which in turn leads to increased wind speeds (relative to those under greedy control) in their respective wakes and, consequently, higher power yield of the affected downstream turbines. The main aim of these concepts is to achieve a net gain, and even small improvements are deemed promising, see, e.g., the wake steering study by Howland et al. (2022) with average power increases of 0.3 to 2.7% for a commercial wind farm.

70

80

In general, it depends on the allocation of the turbines, their characteristics, and the wind conditions whether a control different from the greedy one can indeed yield the desired gains. For example, it may happen that wind speeds are so high that all turbines operate at maximal capacity anyway; nevertheless, some control could then still be meaningful to reduce mechanical loads. Furthermore, there are cases in which axial induction control shows no positive effect on total power output while yaw control yields significant improvements, see the high-fidelity computational fluid dynamics simulations in Gebraad et al. (2015). Thus, we will focus on yaw control in this paper, where changing the yaw angle offset of a turbine deflects its wake.

There is already a lot of research on yaw-based control. We follow the literature distribution in Stanley et al. (2022), which divides it into two parts to tackle the optimization problem, i.e., using continuous vaw angles offsets between lower and upper bounds, see Gebraad et al. (2014); Fleming et al. (2016); Gebraad et al. (2017), and using discretized yaw angles offsets, see Dar et al. (2017); Dou et al. (2020). In Gebraad et al. (2014) a slow game-theoretic approach is used, which does not necessarily deliver a global optimum as desired. This is also not delivered in Fleming et al. (2016); Gebraad et al. (2017) as their optimization method is based on sequential quadratic programming (SQP). However, a combination of yaw control and farm layout optimization has been considered in both references, which is an interesting application but out of scope of the present paper. In Dar et al. (2017), the authors modified the Jensen model (cf. Jensen (1983)) to include the effect of yaw angle offset adjustments and developed a dynamic programming formulation (DPF) to pass the wind speed downstream from turbine to turbine, which results in a very efficient method for turbines in a single row. However, the nonlinearity of the equation to compute the wind speed for a turbine located in several turbine wakes prevents transferring this concept to a 2D farm layout. Nevertheless, Dar et al. (2017) showed that optimizing each row separately with DPF, i.e., ignoring effects in adjacent rows, vields an accuracy of 1% compared to the global optimum reduces the gap between its so-called wind farm efficiency and its globally optimal quantity (obtained by full enumeration)—to up to 1%. This idea to split the farm into disjoint subsets of turbines has already been presented in Spudić and Baotić (2013), which tackles distributed systems, and is also used in Siniscalchi-Minna et al. (2020); Bernardoni et al. (2021); Dong and Zhao (2023). The latter one even allows at least one turbine per subset to be in several subsets, which can lead to conflicting yaw offsets: while they describe a helping logic to handle this, we inherently ensure the yaw offset compatibility for any number of turbines. Our goal is to determine the global optimum—under some mild assumptions, see Sect. 1.2.1 for details—without resorting to full enumeration; for this, our superordinate model takes dependencies of adjacent rows subsets of turbines into account and can integrate any kind of wake effect simulation. In fact, we will consider the farm as a network. This general point of view has already been used in Annoni et al. (2019) for a different application, namely to share information among nearby turbines to improve wind direction estimation; the underlying method, which allows simultaneous clustering and optimization on graphs, was developed in Hallac et al. (2015). In Dou et al. (2020), the covariance matrix adaptation evolution strategy is employed, which is a heuristic algorithm for black-box functions. In contrast, our focus is to exploit the structure of the optimization problem. In Stanley et al. (2022), the structure of the problem is used in the new so-called Boolean approach. This considers which wind turbines have downstream ones in their wake, starts at the upstream-most turbine, and fixes a yaw angle offset to either 0° or 20° if it increases the power of the farm; the simulations used the software FLORIS (cf. NREL (2024)) with the Gauss-Curl-Hybrid wake model (cf. King et al. (2021)). This greedy approach is efficient, but In the adaption—called serial-refine method—, see Fleming et al. (2022), each turbine is run through twice (in a serial and a refine pass), which allows several yaw offsets. This method is fast as well as successful and suitable for a comparison even if it generally does not result in guarantee a globally optimal solutionas it fixes angles sequentially and only allows two yaw angles (although 20° was selected thoughtfully). In contrast, our approach uses a finer discretization and optimizes yaw angle optimizes yaw offset settings simultaneously for the whole farm. (From the view of blade load, which we do not take into account, a slightly positive yaw offset is best, whereas the exact location depends on level of wind shear, see the field study Ennis et al. (2018).)

100

105

110

115

120

Another general idea is to divide the farm into partitions, see Siniscalchi-Minna et al. (2020). This idea goes back to Spudié and Baotié (2013), which tackles distributed systems. We will also consider subsets of turbines but in contrast we allow that a turbine is in several subsets, i.e., the subsets are coupled to exploit their structural connection. In fact, we will consider the wind farm as a network. This general point of view has already been used in Annoni et al. (2019) for a different application, namely to share information among nearby turbines to improve wind direction estimation; the underlying method, which allows simultaneous clustering and optimization on graphs, was developed in Hallac et al. (2015).

#### 1.2 Contributions and limitations

125

130

135

140

155

We provide a method of globally optimal yaw control (under some mild assumptions) that also includes the possibility to deactivate wind turbines, e.g., for maintenance reasons. To that end, we propose a novel superordinate model which exploits the coupled nature of wind turbines in a wind farm and can be based on any wake model.

We refer to the determination of a globally optimal combination of yaw angles offsets for a given wind farm layout and given wind conditions (i.e., subject to arbitrary but fixed wind speed and direction) as wind farm yaw problem (WFYP)a WFYP; see Sect. 2 for details and a mathematical problem definition. In this context, global optimality refers to an objective function, which takes the total power output of the farm into account—our main goal—and can include other quantities representing mechanical loads; in fact, we provide to include the important tower load and the pitch angle changes (causing some wear) as so-called tower activity and pitch activity, see Sect. 3 for a definition; we do not consider the blade load as the used simulation software, described in Sect. 3.1, does not provide a suitable output quantity.

In the following, we paraphrase our problem solving approach after emphasizing what we exploit for this. The complex nonlinearities of wake flow dynamics and turbulence are typically only available through simulation, which makes a direct integration into an optimization model almost impossible. A naive approach to solve the WFYP would amount to simulating the behavior for is to run simulations for every possible combination of the yaw angles yaw offset combination, i.e., full enumeration, but is already impractical for small farms. The crucial observation is that the wake interactions of turbines adhere to certain patterns with respect to the farm layout that occur repeatedly, and with overlaps, across the entire farm. We exploit these redundancies to greatly reduce the number of required combinations: Our our superordinate model constructs the farm on the basis of these patterns of depending turbines and ensures the consistency of selected yaw angles offsets in regions of overlapping patterns; we formulate a corresponding integer program IP to receive the desired yaw angles offsets as solution.

Our numerical experiments are intended as *proof of concept* as we use error-free simulation data. They will show that state-of-the-art solver software for this problem class—e.g., Gurobi, see Gurobi Optimization, LLC (2022), or SCIP, see Bestuzheva et al. (2021)—can solve these WFYP problems within reasonable time, demonstrating the practicality of our approach.

The use of our superordinate model enables deactivating any turbines and a large scaling of the wind farm size orthogonal to the wind direction, whereas a scaling in wind direction significantly increases the computational effort due to a stronger growth of relevant patterns—while beyond the scope of this paper, our model could, in principle, be extended to mitigate the effort required for scaling in wind directionscaling in wind direction is possible by the following idea: split the patterns in segments in wind direction (rows of turbines so to speak), compute the upstream-most segment with specific yaw offsets,

run the simulation, save the resulting wind field, use it to simulate all yaw offset combinations in the next segment and so on. Moreover, the weighting flexibility of the objective function terms (power output and mechanical loads) allows additional objectives to be considered, e.g., putting selected turbines in a low-load operating mode.

## 1.2.1 Assumptions

170

175

180

185

We consider the setting in which all turbines in the wind farm are of the same type and arranged on an underlying irregular grid. These assumptions are not particularly restrictive in practice since, on the one hand, turbines within one farm are typically of the same type—although layout optimization can result in different turbine heights, see, e.g., Stanley et al. (2017)—and on the other hand, we can, in principle, choose the grid resolution as fine as needed to allow representing any layout (by leaving some grid points unused); e.g., the results of layout optimization in Thomas et al. (2015); Gebraad et al. (2017) are not arranged on a simple grid. However, an irregular grid with, e.g., three and five rotor diameters distance between the turbines , respectively, is quite common, see, e.g., Gebraad et al. (2014); Gebraad and van Wingerden (2014); Boersma et al. (2018, 2019b).

Moreover, our model of the WFYP problem relies on two operational assumptions, which can also be realized with arbitrary fine resolution and should therefore not be restrictive in applications: The admissible yaw angles the admissible yaw offsets are bounded—to prevent overly strong mechanical loads, cf., e.g., Boersma et al. (2019a)—as well as discretized, and we impose a threshold below which the influence of wakes on downstream turbines is deemed negligible.

In particular, Fleming et al. (2016) limit the yaw offset to  $[-45^{\circ}, +45^{\circ}]$  and  $[-25^{\circ}, +25^{\circ}]$ , Boersma et al. (2019a) to  $[-25^{\circ}, +25^{\circ}]$ , Stanley et al. (2022) to  $[0^{\circ}, 30^{\circ}]$ , and our industry partner suggests  $[-15^{\circ}, +15^{\circ}]$  to protect the turbines. In our computational experiments, e.g., we choose yaw angles offsets from  $[-15^{\circ}, +15^{\circ}]$  at  $5^{\circ}$  increments and set the downstreammost turbines to  $0^{\circ}$  (to reduce the number of options, see Sect. ??2.1)—we always state yaw angles offsets relative to the (fixed) wind direction, i.e., as yaw offsets with respect to the mathematically positive sense of rotation—and disregard wake influence if the wake-induced wind speed reduction (relative to the given speed) at the downstream turbine is at most 5% or less. We will also refer to this exemplary setup for illustrative purposes when we formally define the WFYP and our solution approach in Sect. 2. Nevertheless, our method admits arbitrary other settings, e.g., discretized yaw angles offsets for the downstream-most turbines.

Our choice is not unrealistic: Quick et al. (2020) describe the problem of uncertainty of incident wind conditions for metrological reasons and for real-world causes; in fact, the inflow of a wind farm can consist of several wind directions, speeds, turbulence intensities—TIs and shears (e.g., caused by a mountain). Stanley et al. (2022) deduce that it is unrealistic to solve the wind farm yaw problem—WFYP with continuous or finely discretized yaw angles offsets and choose their Boolean optimization approach only deciding whether a turbine is yawed or not, i.e., set 0° or 20° (which is a result of power simulations of turbines with a yaw angle offset discretization of 5°); they also compared their approach with a common continuous yaw optimization (based on gradients) and mostly achieve the same power improvement. Against this background, our choice of 5° increments is reasonable.

In general, wind turbulence depends on a number of meteorological and topographical factors, whereas the power output essentially depends on long-term fluctuations and loads are caused by short-term fluctuations, see Hau (2013). We will fix

the turbulence intensity (TI, see Sect. 3.1 for a definition), throughout this paper; a deeper investigation is out of scope for an impression of the locally strong speed fluctuations in the wind field, see Fig. 1. For general effects we refer to the study in Talavera and Shu (2017): first, there is a correlation between the increase of turbulence intensity TI and faster wake recovery (as wind speed recovers faster for turbulent shear flow in comparison to laminar shear flow) and second, turbulent inflow increases the power output of a wind turbine (because of suppressed flow separation).

The correlation between important weather characteristics like temperature, relative humidity, wind speed and wind gusts are investigated in (Vladislavleva et al., 2013, Fig. 2): as expected, wind speed and gusts have a strong positive correlation with the power output while the pressure has a slightly negative correlationone. Finally, the spectrum of possible influences is wide. We focus here on the most influential factors in this paper, i.e., wind speed and direction, and fix the others like turbulence intensity. It and air density for simplicity.

## 1.2.2 Complexity theory point of view and computation time

In fact, while the above-described homogenization of turbines described homogeneous turbine type as well as layout structure, and the yaw angle offset discretization, may seem to simplify the problem, this is not the case from the viewpoint of computational complexity theory: As as we will prove in Appendix A, the WFYP is generally  $\mathcal{NP}$ -hard, which means that an efficient solution algorithm—i.e., one with runtime run time polynomially bounded by the input size—is highly unlikely to exist, cf. Garey and Johnson (1979). This computational intractability result, along with discretization-related aspects, motivates and justifies tackling the WFYP by integer programming IP techniques; see, e.g., Schrijver (1986) for a thorough introduction to integer programming IPs.

Thus, the only remaining potentially limiting aspect is the computation time, which naturally increases with growing problem size and complexity. The assessment of Fleming et al. (2022) for a real-time control scale is of seconds to minutes. Nevertheless, in general, we can exploit several-two mitigating facts: Firstfirst, it is useful to avoid continuous small yaw movements in order to not unduly increase mechanical loads, and second, the yawing rate must be slow (approximately  $0.5^{\circ} \, \mathrm{s}^{-1}$ ) to avoid gyroscopic moments, see (Hau, 2013, Sects. 6.3.1 and 11.3). As a consequence, yaw angles are usually only adjusted at a fairly low rate, e.g., every  $15 \, \mathrm{min}$ , which provides time for solving the WFYP instancewe assume that a computation time of less than 1 min is sufficient; in addition, a light detection and ranging (LIDAR) system could provide wind information at an early stage. As our integer programming-IP approach is capable of determining globally optimal yaw angle-offset combinations for entire wind farms of considerable size at most under one minute (after required precomputations), e.g., 27 wind turbines in 6s11s, it is suitable for real-world application.

#### 1.3 Paper outline

195

200

205

210

215

220

The paper is structured as follows: In Sect. 2, we formulate the wind farm yaw problem (WFYP) mathematically, we motivate and develop our covering approach and the integer program (IP for short). The details on precomputations, i.e., on the simulation and the resulting performance indicators are described in Sect. 3. We explain and discuss the results of However, the practical realization of a short real-time control scale would require a time-delayed yaw offset adaption of each turbine

(depending on the propagation time). In our computational experiments in Sect. 4 and finally, conclude the paper in , we will not consider this transient phase in the but the effects over a longer period of time instead, namely 10 min, see Sect. 5. The theoretical complexity of the WFYP is examined in Appendix A. We abbreviate farm for wind farm and turbine or WT for wind turbine 3.2 for details.

#### 2 The wind farm vaw problem

225

230

245

250

Recall that our wind farm yaw problem (WFYP) WFYP aims to find a set of yaw angles—choosing one of a set of admissible angles for each turbine—that offsets that maximizes the total power output of the farm, optionally along with other quantities, under a given wind scenario, i.e., fixed wind direction and speed. We will formalize this optimization task in the following Sect. 2.1; to that end, we will introduce some notation and an illustrative example that will accompany us throughout the present section. In , develop our CA in Sect. 2.2, we develop our covering approach and derive the corresponding integer program IP in Sect. 2.3.

## 2.1 Notationand, basic WFYP formulation as IP with black-box objective, and the curse of dimensionality

We consider a farm with  $n_{\rm WT}$  turbines, each identified by an index from the set  $T:=\{1,2,\ldots,n_{\rm WT}\}$ . Later, in Example 2.2, we will use our ultimate assumption that turbines are located on an irregular grid with certain spacing in both dimensions. We assign to each turbine  $i \in T$  a set  $\Gamma_i$  of admissible yaw anglesoffsets, see Sect. 1.2.1, with respective size  $n_{\Gamma,i}:=|\Gamma_i|<\infty$ . For every turbine i, we associate an index set  $N_{\Gamma,i}:=\{1,\ldots,n_{\Gamma,i}\}$  with its admissible yaw anglesoffsets. This general notation allows for turbines of different types, but even when working with identical ones, for which the yaw angle offset sets usually coincide, difference may arise, e.g., if maintenance reasons limit the options for specific turbines.

## 2.1.1 WFYP formulation as integer program with black-box objective

depend on the global yaw configuration, i.e., the collection of the set yaw angles offsets of all individual turbines, as well as the considered wind conditions (in particular, direction and speed). Since the precise relation of these aspects has no known analytical form, the objective function of the WFYP must generally be considered a *black-box* whose values for a specific combination of input parameters can be determined, or estimated, by running a simulation of the corresponding farm scenario. To specify a basic mathematical formulation of the WFYP, we introduce binary decision variables  $x_{i,j}$  for all  $i \in T$ ,  $j \in N_{\Gamma,i}$ ; if turbine i is set to the yaw angle offset (from  $\Gamma_i$ ) indexed by j, then  $x_{i,j} = 1$ , and otherwise  $x_{i,j} = 0$ . As any turbine can only operate with one yaw angle offset at a time, these decision variables must adhere to  $\sum_{j \in \Gamma_i} x_{i,j} = 1$  for all  $i \in T$ . The blackbox objective can then be described by a function  $f_\omega : \{0,1\}^{n_{\Gamma,1}+\dots+n_{\Gamma,n_{WT}}} \to \mathbb{R}^{n_{WT}}$ , where we omit the dependency on the (here, fixed) wind direction and speed as well as farm layout for notational convenience and where the vector  $\omega$  consists of two weighting factors, which we will discuss later. This function is comprised of the objective contribution of every turbine, which is impacted by its own yaw angle-offset as well as the yaw configuration of the remaining farm (in fact, not all other turbines influ-

Recalling that the turbines can influence each other, the overall power output of the farm and load-related other quantities

ence any given one, but for now, we do not utilize this). In particular, the function  $f_{\omega}(x) = (f_{\omega,1,j_1}(x), \dots, f_{\omega,n_{\mathrm{WT}},j_{n_{\mathrm{WT}}}}(x))^{\top}$ , where  $f_{\omega,i,j}(x)$  denotes the objective contribution of turbine i when set to yaw angle offset index j from its admissible set  $\Gamma_i$  (as per  $x_{i,j} = 1$ ). Here, the yaw configuration of all turbines (in particular those that influence i) is fixed as prescribed by the decision variables x. To find the optimal yaw configuration of all turbines, i.e., a solution  $x \in \{0,1\}^{n_{\Gamma,1}+\dots+n_{\Gamma,n_{\mathrm{WT}}}}$ , our objective function sums up contributions of individual turbines:

$$f_{\omega}^{\Sigma}(x) := \sum_{i=1}^{n_{\mathrm{WT}}} \sum_{j=1}^{n_{\mathrm{T},i}} f_{\omega,i,j}(x) \, x_{i,j} \quad \text{with black-box simulation function} \quad f_{\omega,i,j}(x) := P_{i,j}(x) - \omega^{(\mathrm{T})} \, a_{i,j}^{(\mathrm{T})}(x) - \omega^{(\mathrm{P})} \, a_{i,j}^{(\mathrm{P})}(x),$$

$$f_{\omega}^{\Sigma}(x) := \sum_{i=1}^{n_{\mathrm{WT}}} \sum_{j=1}^{n_{\mathrm{T},i}} f_{\omega,i,j}(x) \, x_{i,j} \quad \text{with black-box simulation function} \quad f_{\omega,i,j}(x) := P_{i,j}(x) - \omega^{(\mathrm{T})} \, a_{i,j}^{(\mathrm{T})}(x) - \omega^{(\mathrm{P})} \, a_{i,j}^{(\mathrm{P})}(x), \quad (1)$$

where  $P_{i,j}$ ,  $a_{i,j}^{(\mathrm{T})}$  and  $a_{i,j}^{(\mathrm{P})}$  are the average power output, the tower activity, and the pitch activity—all over a certain (fixed) period of time—of turbine  $i \in T$  with yaw angle offset index  $j \in \Gamma_i$  (and the remaining yaw angles offsets corresponding to the selections encoded in x). To evaluate the black-box for a specific x, one needs to resort to *simulation* to obtain the power and mechanical load values for each turbine in the considered farm (under the given wind scenario)—the details, including definitions of the notions of tower and pitch activity, will be described in Sect. 3. The (nonnegative) weighting factors  $\omega^{(\mathrm{T})}$  and  $\omega^{(\mathrm{P})}$  are set a priori and determine the relative importance of the respective quantities in the optimization objective; in particular, both weights can be set to zero to take only the power into account; in addition, we could choose individual weights for each turbine.

Thus, we formulate the wind farm yaw problem (WFYP) as an integer program (IP) WFYP as an IP with black-box objective:

$$\max_{x} \sum_{i=1}^{n_{\text{WT}}} \sum_{i=1}^{n_{\Gamma,i}} f_{\omega,i,j}(x) x_{i,j}$$
 (2)

s.t. 
$$\sum_{j=1}^{n_{\Gamma,i}} x_{i,j} = 1$$
 for  $i = 1, \dots, n_{\text{WT}}$  (3)

$$x_{i,j} \in \{0,1\}$$
 for  $i = 1, ..., n_{WT}$  and  $j = 1, ..., n_{\Gamma,i}$ . (4)

#### 275 **2.1.1** The curse of dimensionality

255

260

265

280

Due to the black-box nature of the objective function, the above formulation cannot simply be handled by off-the-shelf IP solvers. Indeed, we call it the "basic" formulation because it essentially requires computing all  $f_{\omega,i,j}(x)$  to obtain a standard (non-black-box) IP, and hence corresponds to the naive brute-force full enumeration. Clearly, this approach is only viable for very small WFYP instances—i.e., few turbines with a small set of admissible yaw angles—but is expensive for larger instances due offsets—due to the exponential growth of yaw angle offset combinations; see also the Example 2.2 Remark 2.3 given below. Moreover, each simulation run incurs a certain run time that itself increases with the farm size. Thus, the WFYP

Figure 2. Illustration of the  $3 \times 2$  farm layout from Example 2.2; the wind direction is indicated by small arrows. The drawing is true to scale for NREL 5-MW turbines, which have a rotor diameter of D = 126 m, and for a turbine spacing of  $3D \times 5D$ .

suffers from the typical "curse of dimensionality" often encountered in combinatorial problems. In fact, our following result establishes that an efficient (polynomial-time) solution method for the WFYP very likely does not exist; the proof is deferred to Appendix A.

**Proposition 2.1** (Theorem A.3 and Corollary A.4 from Appendix A). The wind farm yaw problem WFYP is strongly  $\mathcal{NP}$ -hard and cannot be approximated within any factor  $\alpha < 1$  in polynomial time (unless  $\mathcal{P} = \mathcal{NP}$ ).

The following example illustrates the WFYP and its "combinatorial explosion", and motivates the circumvention of some complexity issues by the covering approach we will introduce next, in Sect. 2.2. This example, along with some others, will also be used for our computational experiments in Sect. 4.

Example 2.2 (A  $3 \times 2$  farm). We consider  $n_{\rm WT} = 6$  turbines, arranged in a  $3 \times 2$  farm, see Fig. 2; we assume the wind blows from the left side-west to east and we identify the turbines with the index set  $T = \{1, \ldots, 6\}$  as depicted. The turbines may be homogeneous of type NREL 5-MW turbines with a rating value of 5 MW and a rotor diameter of D = 126 m, cf. (Jonkman et al., 2009, Table 1-1). We set the turbine spacing to  $3D \times 5D$ , i.e., turbines are on an irregular grid with three and five rotor diameters distance between turbines in the width ("column") and depth ("row") direction, respectively. We choose the notation analogous to matrices; in the literature, our example would usually be referred to as  $2 \times 3$  with  $5D \times 3D$ . However, the  $3D \times 5D$  spacing choice is common, see, e.g., example farms in Gebraad et al. (2014); Gebraad and van Wingerden (2014); Boersma et al. (2018, 2019b) (also, Katic et al. (1987) mentions 5D as row value but no column value). We restrict the permissible yaw angles to  $\gamma \in [-15^{\circ}, +15^{\circ}]$  at  $5^{\circ}$  increments offsets to  $\gamma_i \in \Gamma_i = \{-15^{\circ}, -10^{\circ}, \dots, +15^{\circ}\}$  and  $n_{\Gamma,i} = n_{\Gamma} := 7$  for every  $i \in T$ .

Remark 2.3 (Total number of possible yaw configurations of a  $3 \times 2$  farm). Example 2.2 yields a total number of  $n_{\Gamma}^{n_{WT}} = 7^6 = 117649$  possible yaw configurations. Consequently, this number of farm simulations would be required to solve the WFYP with the basic approach for one wind scenario. Therefore, we need a different approach to reduce the number of simulations. A coarser yaw angle offset discretization is not an option as it would sacrifice the level of exercisable control. Indeed, our approach achieves this by reducing the number of yaw angle offset combinations to consider and by reusing simulation results where possible.

A turbine has the highest power output with a yaw offset of  $0^{\circ}$  (i.e., it runs greedily), see, e.g., Dar et al. (2017). So, an initial approach that most likely preserves the most power output but reduces the number of options is to let the downstream-most ones run greedily. (We verified by an experiment that the wake of a yawed turbine has no influence on this approach at distance of 3D.) The number of possible yaw configurations in Example 2.2 would then reduce to  $7^3 = 343$ ;

however, such an approach does not scale—a  $3 \times 3$  farm again results in  $7^6$  configurations. This emphasizes the need for an altogether different approach.

In the following subsection, we propose a method that exploits certain structural redundancies with respect to wind wake interactions to significantly alleviate the number of required simulation runs while retaining the global optimality of the WFYP.

## 315 2.2 Section covering Covering approach for WFYP solution

The assumed homogeneous farm layout and composition—i.e., using identical turbines, placed on nodes of an irregular grid—gives rise to certain structural similarities, or reoccurring turbine type and layout structure gives rise to recurring patterns, that can be exploited to equivalently reformulate the WFYP in a way that reduces the number of black-box evaluations (i.e., simulation runs).

## 2.2.1 Downstream and upstream Upstream sections

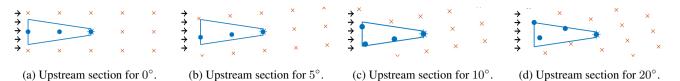

320

325

330

To that end, we take a closer look at the turbines that are influenced influence by a specific turbine, i.e., affected affect the latter by the downstream wind wake<del>of the latter</del>; we call the set of influenced turbines together with the specific one a downstream section. Similarly, we refer to the set of turbines turbines that influence a specific one as an upstream section (including the specific one). Both depend The size depends on the wind conditions (in particular, the wind direction) and the yaw angle offset(s) of the influencing turbine(s). They include It includes all turbines that could be influenced by (as downstream section), or could influence (influence as upstream section), the specific turbine in focus, i.e., sections are the upstream section is based on the admissible yaw angle offset ranges. Moreover, we remind the reader that one assumption is to disregard wake influence if the wake-induced wind speed reduction (relative to the free stream) at the downstream turbine is at most a specific threshold—throughout a threshold or below—throughout this paper, 5%, see Sect. 1.2.1. The concrete chosen area is a trapezoid (for visualization we sometimes use triangles) based on this threshold : For (without guaranteeing it): for this, we simply use the wind speeds at the so-called observation points (from the simulations with  $0^{\circ}$  and extreme yaw offsets, e.g.,  $\pm 15^{\circ}$ ) in the wake, see Sect. 3.1, and set the absolute value of the slope of the trapezoid to at least 0.15, which corresponds to an angle of approximately 8.5°, see Fig. 3. (For a rough comparison, Dar et al. (2017) neglect the deficit in velocity for angles yaw offsets beyond 20° from the center of the turbine based on Jensen (1983).) Finally, the depth of the trapezoid constructed as described above is usually truncated (or, rarely, extended) to match the depth of the farm—in fact, we use the *effective depth* of the wind farm, which we define in Sect. 2.2.3; it coincides with the depth of the wind farm if the wind direction is  $0^{\circ}$  and can be smaller otherwise.

To illustrate down- and upstream sections, reconsider Example 2.2 and its farm in Fig. 2. Under these fixed wind conditions, WTs 4, 5 and 6 are influenced by WT-1, 2, and 3 influence WT 5 depending on the yaw angle γ<sub>2</sub> ∈ [−15°, +15°] offsets in [−15°, +15°], i.e., the downstream section at WT 2 is given by {2,4,5,6}. Similarly, the upstream section at , e.g., WT 5 is given by {1,2,3,5}. The chosen sections are upstream section is useful to explain the concept; in fact, with the selected experimental setup for our results in Sect. 4 the corresponding down- and upstream sections both upstream section would only

**Figure 3.** Down—and upstream Upstream sections (blue trapezoids) with included turbines (marked as points; asterisks are upstream—most (downstream-most)-turbine in downstream (upstream) section) in a grid of turbines (red crosses). The grid represents a farm with infinite expansion.

include WTs 2 and 5, see Figs. ??/Fig. 3(a) for a corresponding farm with three turbines in depth; and Fig. 3 for an overview with wind directions of 0°, 5°, 10° and 20°. In fact, we only consider the downstream section to determine the upstream one, whose pattern is the point reflection of the downstream one on the upstream-most turbine (marked by asterisk).

## 2.2.2 Section configurations

345

350

355

360

365

Depending on the positions of subsets of turbines within the farm (keeping all other aspects fixed), upstream sections can take on different patterns, which can be identified based solely on the grid layout of the farm, see, e.g., Fig. ??. In particular, we can omit (or deactivate) turbines within any upstream section, thereby obtaining what we call *section configurations* as structural subsets of the complete section configuration, i.e., the upstream section itself. Crucially, if all turbines are of the same type, only a single upstream section is needed as a "template" from which to extract the appropriate "patterns" with which the farm can be represented—i.e., we can *cover* the entire farm using (overlapping) section configurations—and simulations can focus on the area of upstream section (reusing simulation results of the section configurations) rather than the whole farm directly. After the following example, we will formalize and explain this *covering approach*CA.

We can cover the  $3 \times 2$  farm from Example 2.2 (cf. Fig. 2) by those section configurations shown in Fig. ??: we anchor the configuration from ?? at WT 5 and the ones from ?? at WTs 4 and 6 (as the respective downstream-most turbine instead of 5), respectively, since the corresponding parts of the farm exhibit the same structural pattern, see also Fig. ??. A change of the farm layout would require other section configurations; e.g., without WT 2 we would need the configuration depicted in Fig. ?? for WT 5, and the one with just two turbines directly behind each other (not depicted) for WTs 4 and 6. In total, for the upstream section, we have 16 possible section configurations, including the complete one and the empty one. In general, if an upstream section encompasses  $n_{\text{WT},u}$  turbines, there is a total of  $n_{\text{WT},u}$  possible section configurations.

As in the example, we only need a small number of the possible section configurations to cover the farm during normal operation. However, we take into account all possible section configurations: it increases the precomputation time but preserves flexibility, i.e., we are prepared for deactivated turbines and can enlarge the farm orthogonal to the wind direction.

## 2.2.3 Covering sections to reduce the computational burden

To formalize the notion of section configurations that are suitable for covering the farm, it suffices to focus on the downstreammost turbines, whose number we denote by  $n_s$ , and determine so-called covering sections anchored at them.

**Definition 2.4** (Covering sections). A covering section is a set  $S_k \subseteq T$  of turbines in a farm that influence each other with respect to (wake) disturbances. We denote the set of covering sections in a farm by  $S := \{S_1, \ldots, S_{n_s}\}$ . Furthermore, we denote the set of those covering sections that contain a specific turbine i by  $S(i) := \{S_k \in S : i \in S_k\}$ .

To cover the farm, we must assign one covering section to each downstream-most turbine, as illustrated in Fig. ??, but as different covering sections can have the same pattern, a section configuration can be used several times, e.g., in Fig. ??. The core advantage of this covering approach CA is the significantly reduced number of simulations required to find the best WFYP solution (in comparison to full enumeration) as we only need to precompute the yaw configurations within every (distinct) section configuration and, accordingly, obtain the simulation results for all covering sections.

We already mentioned that wind directions deviating from  $0^{\circ}$  require to define the *effective depth* of the wind-farm. For illustration, we use a  $3 \times 2$  farm with a wind direction of  $0^{\circ}$  and  $20^{\circ}$ , see Figs. ??/??. In the case of  $0^{\circ}$ , the farm and the corresponding upstream section both have a depth of 5D. For other directions, e.g. as in Fig. ??, this depth changes. The *depth* of the wind-farm is the distance in x-direction between the upstream- and downstream-most turbines inside the wind-farm, i.e., in our example between WTs 3 and 4. The depth of the upstream section is analogously defined inside the upstream section—in our example, WTs 2 and 4. As this depth is sufficient to finally cover the farm we also call it *effective depth of the wind-farm*. Usually, our use of terms "upstream-" and "downstream-most" turbines refers to these covering sections, e.g., in our example, WTs 4 to 6 are the downstream-most ones and serve as anchors for the covering sections. If an anchor turbine is missing, say WT 4, we relocate the covering section, i.e., in our example, we attach  $S_1$  at WT 1 (where  $S_1$  uses the section configuration with only one active turbine). Then we can assume without loss of generality that the downstream-most turbine inside a section configuration is always active, thus circumventing the half of all combinations in which the downstream-most turbine could be inactive. (Alternatively to this relocation, one could have anchored the covering section at a deactivated "virtual" WT 4.)

#### 2.2.4 The required number of simulations

370

375

380

385

390

395

400

Before we turn to the WFYP model based on the covering approach CA, we take a closer look at the required number of simulations to solve it. For simplicity, we assume the same set of admissible yaw anglesoffsets, say,  $\Gamma$  with  $n_{\Gamma} := |\Gamma|$  for the (identical) turbines. In the basic approach for the whole farm with  $n_{\rm WT}$  turbines, we saw below Remark 2.3 that the total number of distinct yaw configurations, which coincides with the required number of simulations, amounts to  $n_{\Gamma}^{n_{\rm WT}-n_s}$  if the  $n_{\rm s}$  downstream-most turbines run greedily. Analogously, again running the downstream-most turbine greedily, an upstream section with  $n_{\rm WT,}$  turbines admits  $n_{\Gamma}^{n_{\rm WT}}$  possible yaw configurations and a covering section  $S_k$  with  $n_{\rm WT,}$  turbines admits  $n_{\Delta,k} := n_{\Gamma}^{n_{\rm WT}}$ .

To solve a single WFYP instance, we perform precomputations, i.e., simulation runs for all yaw configurations on all possible section configurations; recall that we include all possible ones (not only those that occur as covering sections) to preserve flexibility, see Sect. 2.2.2, and thus, we derive the worst-case number of simulations. In addition, we remind-remembering that farm layout and wind conditions (in particular, direction and speed) are fixed for a single WFYP instance. Consequently, while for each scenario, the number of simulations is much lower than in the basic approach, preparing our approach for application

in a variety of wind scenarios for a given farm will still result in a large precomputation time to run all required simulations. However, we propose to store these precomputed simulation results in a database so that data corresponding to any currently encountered scenario can be retrieved efficiently to solve the corresponding WFYP instance in order to update the yaw control.

In the following, we derive the number of combinations (section configurations and corresponding yaw configurations) and the required number of simulation runs. As there are different ways to avoid further redundant computations in specific situations, these numbers are upper bounds and might be further reduced; we will mention some examples of this aspect.

405

420

425

430

An upstream section (i.e., complete section configuration) with  $n_{\mathrm{WT},u}$  turbines has  $n_{\mathrm{WT},u}^2 = 1 \cdot 2^{n_{\mathrm{WT},u}} - 1$  non-empty section configurations. All other section configurations have fewer active turbines than  $n_{\mathrm{WT},u}$ , and, consequently, admit fewer possible yaw configurations (than the complete one), i.e, the number of required simulation runs is smaller than  $(n_{\mathrm{WT},u}^2 = 1) n_{\mathrm{T}}^{n_{\mathrm{WT},u}-1} (2^{n_{\mathrm{WT},u}})$ . We derive the exact worst-case number of simulations needed, i.e., the total count of all yaw configurations for all possible section configurations (for  $n_{\mathrm{WT},u}$  turbines) that are non-empty and have an active downstream-most turbine running greedily (cf. Sect. 2.2.3). The remaining ones can then either be inactive or active with one of  $n_{\mathrm{T}}$  yaw anglesoffsets. Thus, to select  $n \in \{0,1,\ldots,n_{\mathrm{WT},u}-1\}$  active turbines among these, there are  $\binom{n_{\mathrm{WT},u}-1}{n}$  distinct possibilities and, for any selection of  $n_{\mathrm{T}}$  active turbines,  $n_{\mathrm{T}}^{n}$  possible yaw configurations. Thus, the total number of simulations amounts to

415 
$$n_{\text{sim}} := \sum_{n=0}^{n_{\text{WT},u}-1} n_{\Gamma}^{n} \binom{n_{\text{WT},u}-1}{n}.$$
 (5)

In case of our Example 2.2 (3 × 2 farm), see Fig. ??, with  $n_{WT,u} = 4$  turbines in the upstream section, the formula yields  $7^0\binom{3}{0} + 7^1\binom{3}{1} + 7^2\binom{3}{2} + 7^3\binom{3}{3} = 1 + 21 + 147 + 343 = 512 \cdot 7^0\binom{3}{0} + 7^1\binom{3}{1} + 7^2\binom{3}{2} + 7^3\binom{3}{3} = 512$  combinations (i.e., number of simulations imulation runs); this also applies to the  $4 \times 2$  farm, see Fig. ??, and all enlargements orthogonal to wind direction as they build on the same upstream section. In comparison, if all turbines are active (and the downstream-most ones still run greedily), the basic approach (full enumeration) leads to  $n_{\Gamma}^3 = 7^3 = 343$  required simulations (for  $3 \times 2$ ) and to  $7^4 = 2401$  (for  $4 \times 2$ ), which seems to be a better choice for the  $3 \times 2$  farm. However, the covering approach CA already includes the possibility to deactivate any turbines, see Sect. 2.2.3. If this were included in the basic approach, we would end up with  $(n_{\Gamma} + 1)^3 \cdot 2^3 = 8^3 \cdot 2^3 = 4096$  combinations (for  $3 \times 2$ ) and  $8^4 \cdot 2^4 = 65536$  (for  $4 \times 2$ ). Thus, we expect that the covering approach CA provides a significantly higher efficiency than the basic approach for most real-world farm layouts and wind directions.

Recall that we need these precomputations for each wind condition, in particular, we focus on direction and speed, see Sect. 1.2.1. Usually, these are also discretized in a wind rose, see, e.g., the figures in Zhang et al. (2014); Fleming et al. (2016), which is a circular histogram with the distribution of directions and speeds (e.g., in 5° and 1 m s<sup>-1</sup> steps from 3 to 20 m s<sup>-1</sup>; lower/higher speeds whereas extreme speeds are summarized separately, see Gebraad et al. (2017)). Analogously to the yaw angle offset discretization, a finer discretization is possible but questionable because of due to the uncertainty of incident wind conditions as discussed in Sect. 1.2.1.

#### 2.3 Formulation of the covering approach as an integer program IP

435

440

445

455

460

It remains to formalize how we can use the covering sections to solve the WFYP globally optimal. So, recall the idea to represent the farm as a set of overlapping covering sections (cf. Def. 2.4) rather than of single turbines. Instead of deciding directly on the yaw angle offset of each turbine, decision variables assign a specific yaw configuration to each covering section. For the consistency of the farm covering, we require that each turbine in intersecting parts of different covering sections consistently has the same yaw angle offset in these. This, together with the requirement that each covering section is assigned exactly one yaw configuration, mirrors the constraint of the basic approach that each turbine can only be set at one yaw angle offset, cf. Eqs. (2) to (4).

#### 2.3.1 Contributions of wind turbines located at overlaps of covering sections

Recall that in the basic WFYP approach, the objective function has coefficients (from simulations) for each turbine and yaw angle offset configuration. Now, we have contributions related to assigning yaw configurations (with respect to the underlying section configuration) to covering sections. To avoid multiple counting of the individual contributions of turbines located at overlaps of covering sections, which are available from the simulation results (see vector-valued function  $f_{\omega}$  in Sect. ??2.1), we consider the covering sections in order of their indices  $(S_1, S_2, \ldots, S_{n_s})$  and construct the objective by only adding contributions of turbines in a current covering section  $S_k$  if they were not already contained in the previous covering sections  $S_1, \ldots, S_{k-1}$ . Let  $T_k := S_k \setminus (\bigcup_{m=1}^{k-1} S_m)$  denote the set of new turbines in covering section  $S_k$ ; e.g., in the example from Fig. ??, it holds that  $T_1 = \{1, 2, 4\}, T_2 = \{3, 5\}$ , and  $T_3 = \{6\}$ . Then, we can express the WFYP objective value of a given yaw configuration assignment (one  $\ell_k$  for each respective covering section  $S_k$ ) with our previously-used black-box function as

450 
$$\sum_{k=1}^{n_{s}} \sum_{i \in T_{k}} f_{\omega,i,j(\ell_{k})}(x(\ell_{k})), \tag{6}$$

where  $x(\ell_k)$  stands for the individual-turbine yaw angle offset settings across covering section  $S_k$ , which now depend on the yaw configuration  $\ell_k$  given for each section  $S_k$ , and  $j(\ell_k)$  is the corresponding yaw angle offset index of turbine i.

## 2.3.2 Compatibility of yaw configurations in covering sections

The following paragraphs We will discuss the consistency of the farm covering. In doing so, we will, whereby we describe the details of the covering approach outlined above CA and lead up to the integer program IP (8) to (11). Again, for simplicity, we assume the same set of admissible yaw anglesoffsets, say,  $\Gamma$  with  $n_{\Gamma} := |\Gamma|$  for the (identical) turbines WTs. The appropriate covering sections (and required underlying configuration sections) are defined before building the integer programming model IP model building, recall Sect. 2.2.3.

To specify the IP model, we need additional notation. For a covering section  $S_k \subseteq T$   $(k = 1, ..., n_s)$  with  $n_{WT,k}$  turbines, we identify the yaw configurations inside  $S_k$  by indices  $\ell_k = 1, 2, ..., n_{\Delta,k}$  with  $n_{\Delta,k} := n_\Gamma^{n_{WT,k}-1}$  (as defined in Sect. 2.2.4). Let  $\gamma_i(\ell_k)$  denote the yaw angle offset assigned to turbine  $i \in S_k$  under yaw configuration  $\ell_k$ . For consistency of the global yaw configuration as a composition of sectional yaw configurations, the yaw configurations of overlapping covering sections must

**Table 1.** Lexicographic indexing for the  $n_{\Delta,1} = 3^2 = 9$  yaw configurations for the underlying section configuration to covering section  $S_1 = \{1, 2, 4\}$  in the  $3 \times 2$  farm Example 2.2, cf. Fig. ??, with simplified  $\Gamma = \{-15^{\circ}, 0^{\circ}, +15^{\circ}\}$  (and WT 4 fixed to  $0^{\circ}$ ).

$\ell_1$	1	2	3	4	5	6	7	8	9
WT 1	-15°	-15°	-15°	0°	0°	0°	+15°	+15°	+15°
WT 2	$-15^{\circ}$	0°	$+15^{\circ}$	$-15^{\circ}$	0°	$+15^{\circ}$	$-15^{\circ}$	0°	$+15^{\circ}$
WT $4$	0°	0°	0°	0°	0°	0°	0°	0°	0°

match on the yaw angles offsets of turbines located in the respective intersection. To that end, if the yaw configuration  $\ell_k$  was selected for  $S_k$ , then, for any  $S_{\hat{k}}$  with  $S_{\hat{k}} \cap S_k \neq \emptyset$  for  $\hat{k} \neq k$ , only a subset of yaw configurations is compatible with this selection, namely those  $\ell_{\hat{k}} \in \{1,2,\ldots,n_{\Delta,\hat{k}}\}$  for which the yaw angles offsets  $\gamma_i(\ell_{\hat{k}}) = \gamma_i(\ell_k)$  for all WTs  $i \in S_{\hat{k}} \cap S_k$ . In fact, it suffices to enforce these conditions explicitly for directly adjacent pairs of covering sections (which explicitly excludes an arbitrary order), if they are numbered in ascending sequence in accordance with the downstream-most turbines (say,  $1,\ldots,n_s$  from left to right from behind the farm looking against the wind direction). Then, establishing consistency of the respective overlaps of  $S_k$  and  $S_{k+1}$  by resorting to valid yaw configurations for  $S_{k+1}$  (defined relative to  $S_k$  and each  $\ell_k$ ), for  $k=1,\ldots,n_s-1$ , is indeed enough to guarantee global consistency, which has to overcome the sequential order and is realized in Eq. (10), as by construction, for any WT  $i \in S_{\hat{k}} \cap S_k$  with  $\hat{k} \geq k+2$ , necessarily also WT  $i \in S_{k+1}$ . In addition to  $L_k := \{1,2,\ldots,n_{\Delta,k}\}$ , the index set of all possible yaw configurations for  $S_k$ , we therefore also need the set of valid (or compatible) yaw configurations for  $S_{k+1}$  relative to  $S_k$  with  $\ell_k \in L_k$ , which we denote as  $\tilde{L}_{k+1,\ell_k} := \{\ell_{k+1} \in L_{k+1} : \gamma_i(\ell_{k+1}) = \gamma_i(\ell_k)$  for all  $i \in S_{k+1} \cap S_k\}$ . For  $S_1$ , all possible yaw configurations in  $L_1$  are already valid, i.e.,  $\tilde{L}_1 = L_1$ , as  $S_1$  has no "preceding" covering section. Tables with these dependencies, i.e., the set of valid yaw configurations  $\tilde{L}_{k+1,\ell_k}$  for the current covering section (numbered as k+1) in dependence of the previous one (numbered as k) and its chosen yaw configuration  $\ell_k$ , can be computed straightforwardly.

465

480

To illustrate the notions, we use Example 2.2 (3  $\times$  2 farm) again. For each covering section, marked in Fig. ??, we need to uniquely identify every possible yaw configuration with an index, e.g., by sorting them lexicographically with respect to the yaw angles offsets (in increasing order of the turbine indices); Table 1 shows an example for covering section  $S_1$ , assuming for simplicity  $\{-15^{\circ},0^{\circ},+15^{\circ}\}$  as admissible yaw angles—downstream-most offsets—downstream-most turbines (4, 5, and 6) are fixed to  $0^{\circ}$ , cf. Sect. 1.2.1.

Assuming the same lexicographic indexing to the yaw configurations for each section configuration (and thus for the covering sections), we can determine the sets of valid yaw configurations; Table 2 shows the sets  $\tilde{L}_{k+1,\ell_k}$  for our simplified example. For instance, if yaw configuration  $\ell_1=3$  was used for  $S_1$ , then only those yaw configurations for  $S_2$  in which turbines 1 and 2 also have yaw angles offsets  $-15^\circ$  and  $+15^\circ$ , respectively, are valid for  $S_2$ ; with the used indexing, this amounts to  $\tilde{L}_{2,3}=\{7,8,9\}$ . For  $\ell_2=7$ , only yaw configuration  $\ell_3=1$  is valid; indeed,  $\tilde{L}_{3,7}=\tilde{L}_{3,1}=\tilde{L}_{3,4}=\{1\}$ , as these yaw configurations for  $S_2$  set both turbines 2 and 3 to  $-15^\circ$ , for which the only compatible (and hence, valid) yaw configuration for  $S_3$  is precisely  $\ell_3=1$ .

Table 2. Valid yaw configurations  $\tilde{L}_{k+1,\ell_k}$  of covering section  $S_{k+1}$  (depending on yaw configuration  $\ell_k$  of the previous one  $S_k$ ) compared to all possible yaw configurations  $L_{k+1}$  of  $S_{k+1}$  for the  $3\times 2$  farm from Example 2.2, Fig. ??, assuming admissible yaw angle offset offsets  $\{-15^\circ,0^\circ,+15^\circ\}$  (simplified for the example) for every turbine, fixed angle yaw offset  $0^\circ$  for downstream-most turbines and yaw configurations being indexed in lexicographical order. For  $S_1$ , all possible yaw configurations  $L_1 = \{1,2,\ldots,9\}$  are also valid by design, i.e.,  $\tilde{L}_1 = L_1$ .

k	1	1	1	 1	2	2	2	 2
$\ell_k$	1	2	3	 9	1, 4, 7	2, 5, 8	3, 6, 9	 21, 24, 27
$L_{k+1}$	$\{1, \dots, 27\}$	$\{1,\ldots,27\}$	$\{1,\ldots,27\}$	 $\{1,\ldots,27\}$	$\{1,\ldots,9\}$	$\{1,\ldots,9\}$	$\{1,\ldots,9\}$	 $\{1,\ldots,9\}$
$\tilde{L}_{k+1,\ell_k}$	{1,2,3}	$\{4, 5, 6\}$	$\{7, 8, 9\}$	 $\{25, 26, 27\}$	{1}	{2}	{3}	 {9}

## 2.3.3 WFYP formulation as regular integer programIP

Now, we introduce binary decision variables  $y_{k,\ell_k}$  that encode whether covering section  $S_k$  is assigned yaw configuration  $\ell_k$  490  $(y_{k,\ell_k}=1)$  or not  $(y_{k,\ell_k}=0)$ . Using these variables, the black-box objective function, cf. Eq. (2), can be replaced by a fully linear one once we have precomputed the simulation results for the section configurations. Indeed, the simulation results allow us to specify cost coefficients  $c_{k,\ell_k}$  for every pair of a covering section  $S_k$  and any one of its associated yaw configurations  $\ell_k$ ; in order to avoid counting the objective contributions of turbines within intersecting parts of different covering sections multiple times, we again use a summation that only considers contributions of new turbines in a covering section, cf. Eq. (6):

495 
$$c_{k,\ell_k} := \sum_{i \in T_k} f_{\omega,i,j(\ell_k)}(x(\ell_k)).$$
 (7)

To achieve a globally optimal yaw configuration for the whole farm, we now have to optimize over all compatible combinations, see Sect. 2.3.2, of covering section and yaw configuration assignments (each of which has one associated coefficient  $c_{k,\ell_k}$  and one decision variable  $y_{k,\ell_k}$ ). This yields the following integer linear program to solve the WFYP:

$$\max_{y} \sum_{k=1}^{n_{s}} \sum_{\ell_{k}=1}^{n_{\Delta,k}} c_{k,\ell_{k}} y_{k,\ell_{k}}$$
(8)

500 s.t. 
$$\sum_{\ell_1=1}^{n_{\Delta,k}} y_{k,\ell_k} = 1$$
 for  $k = 1, \dots, n_s$ , (9)

$$0 \le \sum_{\ell_{k+1} \in \tilde{L}_{k+1}, \ell_k} y_{k+1, \ell_{k+1}} - y_{k, \ell_k} \le 1 \qquad \text{for } k = 1, \dots, n_s - 1 \quad \text{and} \quad \ell_k = 1, \dots, n_{\Delta, k},$$

$$(10)$$

$$y_{k,\ell_k} \in \{0,1\}$$
 for  $k = 1, ..., n_s$  and  $\ell_k = 1, ..., n_{\Delta,k}$ . (11)

Constraints (9) ensure that exactly one yaw configuration is selected for each covering section, analogously to Eq. (3). Constraints (10) ensure compatibility as they enforce the selected yaw configuration for a covering section  $S_{k+1}$  to be *valid* with respect to the yaw configuration chosen for its preceding one  $S_k$ , as described in Sect. 2.3.2: If if  $y_{k,\ell_k} = 1$ , i.e.,  $S_k$  uses

yaw configuration  $\ell_k$ , then for  $S_{k+1}$ , a yaw configuration from  $\tilde{L}_{k+1,\ell_k}$  must be selected, i.e., one of the associated binary variables—and hence, their sum—must be one. If  $y_{k,\ell_k} = 0$ , the constraint imposes no restriction with respect to  $\tilde{L}_{k+1,\ell_k}$ .

Finally, we emphasize that both the black-box IP (2) to (4) and the regular IP (8) to (11) are different formulations of *the same problem*, i.e., the WFYP; as such, they are equivalent\_equivalent\_strictly speaking, this is only true if we take into account even the smallest wake-induced wind speed reduction to determine the upstream section instead of our practical assumption in Sect. 1.2.1; an example in Sect. 4 illustrates this small model inaccuracy. Nevertheless, the covering approach CA exploits the problem structure in a way that can significantly reduce the required number of simulations and enables the utilization of modern IP solvers to perform efficient implicit enumeration by branch and bound, thereby avoiding total full enumeration.

## 3 Simulation

We obtain the simulation function output from simulation software; in principle, our approachallows to employ *any* suitable simulation which is interchangeable in our approach. Moreover, recall that our WFYP integer programs (Eqs. IPs (2) to (4) or (8) to (11)) need simulation function values for different yaw angle offset configurations. As we control the yaw anglesoffsets, we only denote the corresponding decision variables *x* as simulation function arguments; the other inputs (farm layout, wind direction and speed) will be made clear in our experiments. In the following, we also introduce other conditions (and used fixed values) on which the simulation also depends, along with the corresponding fixed values we used. We describe the simulation software and our parameter setup in Sect. 3.1. Then, in Sect. 3.2, we specify relevant simulation outputs and define performance indicators based on them, which are combined to form the simulation function.

#### 3.1 Simulation software and parameter setup

For the wind-farm simulations, we used the software package WinFaST<sup>2</sup>. This simulation framework requires a fixed farm layout, yet setting individual parameters for axial. Axial induction and yaw angles is generally possible offsets can be set time-dependent. As our focus lies on optimal yaw anglesoffsets, we leave the greedy control with respect to axial induction to the local controller. The dynamic wake model of WinFaST is based on FLORIDyn, see Gebraad and van Wingerden (2014). As FLORIDyn, it uses so-called observation points to compute local wake characteristics and wake interaction is based on Katic et al. (1987). The turbine controller in WinFaST is inspired by Jonkman et al. (2009), which is widely used for NREL 5-MW turbines, extended by the options (not used by us) to reduce the power and damp tower oscillations, each with respect to its

<sup>&</sup>lt;sup>1</sup>The upper bound in Eq. (10) is redundant: we investigated the effects for  $6 \times 3$  to  $9 \times 3$  farms as in series 2, see Table 6; the redundant conditions slightly increase or decrease (in two out of four cases each) the solving time of the IPs if Gurobi is used as solver, e.g., for  $9 \times 3$ , 11.25s namely (in s) 0.25 (instead of 14.69s0.22), 1.17 (1.09), 3.79 (3.50), 10.77 (10.48), but significantly decrease it for this case in three out of four cases with SCIP, namely (9071.55s instead of 20812.22s); in the other cases SCIP is slower with the redundant conditions s) 18.57 (e.g. 21.45), for  $8 \times 3154.28$  (156.47), 1760.04s instead of 838.63s436.67 (446.62), 3278.30 (1781.71).

<sup>&</sup>lt;sup>2</sup>The MATLAB package WinFaST (Wind Farm Simulation Tool), written by Bastian Ritter and Thorsten Schlicht, is proprietary software for company-internal use at our industry partner IAV GmbH, who provided it to us for experimentation within the joint MOReNet project.

own respective turbine. Moreover, WinFaST uses a modified version (to include yaw control and effects) of the dynamic wind turbine model by Ritter et al. (2016, 2018). The wind field in WinFaST is simulated by Veers method, see Veers (1988).

We denote the average wind speed value of the (horizontal) ambient wind field by  $U_{\rm ave}$ . The turbulence intensity (TI)  $\overline{\rm TI}$  is defined as  $I=\sigma/U_{\rm ave}$ , where  $\sigma$  is the associated standard deviation; it depends on the average wind speed, the roughness of the surface, the atmospheric stability, and the topography, see, e.g., (Hau, 2013, Sect. 13.4). The software WinFaST uses the same parametric model parameters for turbine and wake as in (Gebraad and van Wingerden, 2014, Table 1), that were adjusted for  $8\,\mathrm{m\,s^{-1}}$  with a TI of 6%, with the exception of the air density, which is set to  $1.225\,\mathrm{kg\,m^{-3}}$  as in (Jonkman et al., 2009, Appendix B.1). In our exemplary experiments, we fix the TI to 6%.

#### 3.2 Performance indicators and simulation function

535

It takes a while for the wake of the upstream-most turbine(s) to reach the downstream-most one within the upstream section. Thus, we need to choose a sufficiently long *simulation time interval* [ $t_{s_1}$ ,  $t_{s_2}$ ], depending on the wind speedand farm layout; here, we used 9 min, the TI, and upstream section layout. Moreover, for data analysis and as yaw angles offsets are adjusted at a fairly low rate, we are only interested in the simulation part in which the wake already influences the downstream-most turbine. Also, the wind field is equipped with turbulence and the turbines produce some, so we analyze data over an *observation* time interval [ $t_{o_1}$ ,  $t_{o_2}$ ]. In our case, this includes the middle 5 min of our simulation time interval; we use it to compute the performance indicators and to define our simulation function. In practice, we round the minimal wind speed in the wind field down to  $0.5 \, \mathrm{m \, s^{-1}}$  (namely, 4.5.9, and  $10 \, \mathrm{m \, s^{-1}}$  for speeds of 6.11, and 12 with a TI of 6%) and simulate with this speed and a TI of 0% to round up the resulting propagation time in minutes to finally set a robust value for  $t_{o_1}$ , see Table 3 in Sect. 4 for examples. As we choose a duration of  $10 \, \mathrm{min}$  (to obtain roughly the specified wind speed on a mean at WT 3, cf. Table 3), we end up with  $t_{o_2} = t_{o_1} + 10 \, \mathrm{min}$  and  $[t_{s_1}, t_{s_2}] = [0, t_{o_2}]$ .

The performance indicators (cf. Eq. (13) later) consist of the following three outputs of WinFaST: The *power* generated by each turbine is given in the unit W as function  $p_x:[t_{s_1},t_{s_2}]\to\mathbb{R}^{n_{\mathrm{WT}}}$ . To compute loads we use the *velocity of the nacelle* in unit  $\mathrm{m}\,\mathrm{s}^{-1}$  in wind direction,  $v_x:[t_{s_1},t_{s_2}]\to\mathbb{R}^{n_{\mathrm{WT}}}$ , and the *blade pitch angle* in the unit degree,  $\beta_x:[t_{s_1},t_{s_2}]\to\mathbb{R}^{n_{\mathrm{WT}}}$ .

Now, we define the three performance indicators for each turbine i as averages over the observation time interval  $[t_{o_1}, t_{o_2}]$ , namely the power (output)  $P_i$  (in MW), the *tower activity*  $a_i^{(\mathrm{T})}$ , and the *pitch activity*  $a_i^{(\mathrm{P})}$ . The tower load is high when the nacelle is oscillating; therefore, we use the absolute value of the nacelle velocity v to estimate the tower load by the so-called tower activity. The pitch rate should be kept within limits because of the load of the pitch actuators; therefore, similarly, we use the absolute value of the velocity of the blade pitch angle  $\beta$  to estimate the load of the pitch actuators by the so-called pitch activity. The performance indicators are defined as follows:

$$560 \quad P_i(x) := \frac{1}{t_{o_2} - t_{o_1}} \int\limits_{t_{o_1}}^{t_{o_2}} 10^{-6} \, (p_x(t))_i \, \mathrm{d}t, \quad a_i^{(\mathrm{T})}(x) := \frac{1}{t_{o_2} - t_{o_1}} \int\limits_{t_{o_1}}^{t_{o_2}} |(v_x(t))_i| \, \mathrm{d}t, \quad a_i^{(\mathrm{P})}(x) := \frac{1}{t_{o_2} - t_{o_1}} \int\limits_{t_{o_1}}^{t_{o_2}} \left| \frac{\mathrm{d}}{\mathrm{d}t} (\beta_x(t))_i \right| \, \mathrm{d}t.$$

$$P_{i}(x) := \frac{1}{t_{o_{2}} - t_{o_{1}}} \int_{t_{o_{1}}}^{t_{o_{2}}} 10^{-6} (p_{x}(t))_{i} dt, \quad a_{i}^{(T)}(x) := \frac{1}{t_{o_{2}} - t_{o_{1}}} \int_{t_{o_{1}}}^{t_{o_{2}}} |(v_{x}(t))_{i}| dt, \quad a_{i}^{(P)}(x) := \frac{1}{t_{o_{2}} - t_{o_{1}}} \int_{t_{o_{1}}}^{t_{o_{2}}} \left| \frac{d}{dt} (\beta_{x}(t))_{i} \right| dt. \quad (12)$$

The respective units of tower and pitch activity are  $m s^{-1}$  and  $\circ s^{-1}$  but have no physical meaning.

Finally, we define the weighted sum of these three performance indicators as the simulation function depending on the control input, i.e., the decision variables x. Recall that the dependence on yaw configurations also includes that of a turbine  $i \in T$  on its own yaw angleoffset, which can be expressed using the yaw angle offset index  $j \in n_{\Gamma,i}$ . Therefore, following the notation introduced in Sect. 2.1, we write  $P_{i,j}(x)$ ,  $a_{i,j}^{(\Gamma)}(x)$  and  $a_{i,j}^{(P)}(x)$ . With weights  $\omega = (\omega^{(\Gamma)}, \omega^{(P)}) \in \mathbb{R}^2_{\geq 0}$  for the activity terms the entries of the simulation function, which yields the black-box function to maximize, are:

$$f_{\omega,i,j}(x) := P_{i,j}(x) - \omega^{(T)} a_{i,j}^{(T)}(x) - \omega^{(P)} a_{i,j}^{(P)}(x).$$
(13)

It represents our two main objectives when controlling the farm: maximizing the total power output and minimizing the turbines' mechanical load; the weights balance these typically conflicting objectives. For clarity of notation, we omitted individually weighting the turbines In fact, they could even do this individually for each turbine. Moreover, for simplicity, we focus on the power output, i.e., we set usually  $\omega^{(T)} = \omega^{(P)} = 0$  in Sect. 4. In practice, one "simulation run" consists of evaluating the (vector-valued) simulation function  $f_{\omega} : \{0,1\}^{n_{\Gamma,1}+\dots+n_{\Gamma,n_{\mathrm{WT}}}} \to \mathbb{R}^{n_{\mathrm{WT}}}$  (with entries of the form  $f_{\omega,i,j}(x)$ ) once for the associated section and assignment of decision variables x.

#### 4 Computational results

565

580

585

This section presents four series of computational experiments in a farm for our covering approach: In In order to obtain computational results, we show the overall process in Fig. 6 as it is a combination of CA, see Sect. 4.1, we consider optimizing yaw angles for different wind directions (series 1). In 2.2, its formulation as IP, see Sect. 4.2, we demonstrate that reusing some precomputed simulationresults of series 1 enables our covering approach to enlarge farms orthogonal to the wind directionand to handle cases with deactivated turbines (series 2). In this context, we also investigate the influence of the farm size on the solving time to assess how the theoretical complexity of the WFYP is reflected in practice. In series 3, we consider different wind speeds, 2.3, and simulation, see Sect. 3.

All computations were carried out on a Linux workstation with an Intel(R) Core(TM) i7-6700 CPU with 3.40 GHz (4 we experiment with a wider range of yaw angles and a finer discretization, see Sect. 4.4. cores, 8 threads) and 32 GB memory. The precomputations (simulation runs) were done using MATLAB R2024b, utilizing parallelization of 4 workers. The IPs resulting from our CA were solved with state-of-the-art IP solvers, namely the open-sourced academic solver SCIP 8.0.3, utilizing the LP solver SoPlex 6.0.3, which only supports single-thread, see Bestuzheva et al. (2021), as well as the proprietary Gurobi 10.0.0, which can employ all threads, see Gurobi Optimization, LLC (2022).

- 1. Setup: set a wind direction, speed, and TI, e.g., 6%; choose a farm layout (e.g.,  $6 \times 3$ ) and admissible yaw offsets.
- 2. Preparation and precomputation:
  - (a) Determine the size of the upstream section (for a TI of 0% with  $0^{\circ}$  and the extremes as yaw offsets), see Sect. 2.2.1.
  - (b) Set the observation and simulation time intervals with respect to the propagation time and the TI, see Sect. 3.2 and Table 3.
  - (c) Determine the section configurations, i.e., all patterns of the upstream section, see Sect. 2.2.2.
  - (d) Precomputation: run simulations for all yaw configurations on all possible section configurations, see Sect. 2.2.4.
  - (e) Evaluate the precomputations in the observation time interval to set up the simulation function, see Sect. 3.2.
- 3. Determine the covering sections, i.e., the required section configurations to cover the farm, see Sect. 4.3, and finally, in series 2.2.3.
- 4. Formulate the CA as an IP, see Sect. 2.3.

610

5. Solve the IP (e.g., with Gurobi in less than 1 min); for comparison, simulate the entire farm with baseline and optimized yaw offsets.

Figure 6. Overall process to obtain computational results (as combination of CA, IP formulation, and simulation).

Before we discuss the results, we briefly summarize the most important parts of the overall experimental setup. As admissible yaw angles offsets we choose γ ∈ Γ = {-15°, -10°, ..., 15°} for NREL 5-MW turbines with a rotor diameter of D = 126 m, see (Jonkman et al., 2009, Table 1-1), in different farm layouts from 6 × 3 to 9 × 3 with a turbine spacing of 3D × 5D. In all figures, we display wind direction as blowing from left to right; the actual wind direction is then reflected as a "rotation" of the relative layout placement of a farm by a corresponding amount of As wind directions we use 0°, 5°, 10° or 20°, respectively, where 0° represents wind blowing from west to east. In all figures, we indicate the wind direction by a vector. As average wind speeds we consider 6, 11, and 12 m s<sup>-1</sup>. Deviations from this setup are made clear where they occur. Finally, we frequently compare the optimized yaw offsets against the baseline, i.e., yaw offsets of 0°.

All computations were carried out on a Linux workstation with an Intel(R)Core(TM)i7-6700 CPU with 3.40 GHz (4 cores, 8 threads)

The main computational experiments in a farm with our CA are in Sections 4.1 to 4.4: for different wind directions, for reused precomputed simulations to demonstrate flexibility, for different wind speeds, and for different yaw offset discretizations. However, we begin with some experiments to compare the WinFaST simulation with the software FLORIS, see NREL (2024), and continue with a validation of our CA on the basis of the simulation software FLORIS by comparison with serial-refine (available in FLORIS), see Fleming et al. (2022), and full enumeration (as assumptions and discretizations were employed to arrive at our IP model for the WFYP via the CA).

To that end, we consider a  $3 \times 3$  farm with different TIs, wind speeds and directions and compare the baseline simulations of WinFaST and 32GB memory. The precomputations (simulation runs) were done using MATLAB R2023a FLORIS in Table 3; see Fig. 7(a) for a visualization of part c). In detail, we use the available file gch.yaml as input in FLORIS, i.e., the Gauss-Curl-Hybrid model for wakes but set the wind shear to 0. While the results are similar at WT 3, they differ significantly at WTs 5, and 7 as WinFaST generates a wind field and uses dynamic models for turbines and wakes whereas FLORIS generates no wind field and is restricted to static models, whereby the wake model is sophisticated. Simulation is a complex topic, e.g., WinFaST simulates

that WT 3 sometimes reaches 5MW during observation due to turbulence in parts c) to f). A comprehensive comparison of the simulations (and which one is preferable) is out of scope of the present paper.

615

620

625

630

635

For the mentioned CA validation with FLORIS software simulation, we consider a  $3 \times 3$  farm with a wind speed of  $11 \,\mathrm{m\,s^{-1}}$  and a wind direction of  $20^\circ$ , i.e., the controlled WTs are 2, utilizing parallelization. 3, 5, and 6, cf. the assumptions in Sect. 1.2.1. For the results we refer to Table 4 a) to c) and Fig. 7. The full enumeration takes 9.1 min and results in four solutions with an optimized total power output of  $38.66 \,\mathrm{MW}$ . The IPs resulting from our covering approach were solved with state of the art IP solvers, namely the open-sourced academic serial-refine method also results in  $38.66 \,\mathrm{MW}$ . In particular, we allow seven yaw offsets in the first phase, i.e., our usual choice of  $5^\circ$  steps, and two yaw offsets in the second phase, which practically corresponds to  $2.5^\circ$  steps, which is actually used for WT 2. This method takes only  $1.07 \,\mathrm{s}$ . Our CA predicts a power of  $38.69 \,\mathrm{MW}$ , but the full farm simulation with the optimal yaw offsets also results in  $38.66 \,\mathrm{MW}$ . The CA takes  $1.9 \,\mathrm{min}$  for precomputation and  $0.12 \,\mathrm{s}$  for the IP solver SCIP, which is not directly comparable to serial-refine as we designed the CA with flexibility in mind, see Sect. 2.2.2. All in all, both serial-refine and CA have found a global solution.

The deviations of the predicted power by CA and full farm simulation (in baseline and/or optimization) are limited and are due to the size of the upstream section, which influences the accuracy of the discretized, section-based WFYP model and therefore is a compromise in terms of accuracy and run time. For example, the covering section (based on upstream section Fig. 3(d)) anchored at WT 4 includes WT 2, but WT 1 is marginally outside. An increase in size of the upstream section would ameliorate the small model inaccuracy, but also significantly increase the precomputation time. Therefore, we accept small inaccuracies in the predicted power output by CA (and run full simulation with optimized yaw offsets at the end). As the improvements over the baseline are significantly larger than the deviations from full farm simulation, the optimal solutions of our CA will likely still be optimal for a model using increased upstream sections, though suboptimality is technically possible. The IP solver run times themselves will indicate that handling larger upstream sections should not pose an issue.

We would like to present a case where our CA method is more advantageous in terms of accuracy than the fascinatingly fast serial-refine method. In theory, there could be such a case as our CA is equivalent to full enumeration for sufficiently large upstream sections, see Sect. 2.3.3. However, we have not yet found such an example.

For the remaining paper we show results of our CA approach using WinFaST simulation for computations and visualizing the results with software FLORIS. For the example above, we receive other optimized yaw offsets, see Table 4 d) and Fig. 7(b), where the precomputation takes 4.5h and the IP solver SCIP 8.0.3, utilizing the LP solver 0.11s. These yaw offsets as input in FLORIS result in 38.27MW, which is below the baseline with SoPlex6.0.3, which only supports single-thread, see

Bestuzheva et al. (2021), as well as the proprietary Gurobi 10.0.0, which can employ all threads, see Gurobi Optimization, LLC (2022)

-FLORIS, and demonstrates the dependency of the solution on the selected simulation. In addition, we use the introduced weights ω = (ω<sup>(T)</sup>,ω<sup>(P)</sup>) = (100,10) once to take into account the tower activity and pitch activity in optimization, cf. Eq. (13), see Table 4 e). A detailed comparison to d) with our default ω = (0,0) shows that both tower and pitch activity are decreased, namely to 0.1105 (from 0.1108) and 0.3865 (0.4070) for the price that the power is also decreased (to 33.03 from 33.05 MW).

**Table 3.** Data and results for baseline simulations of a  $3 \times 3$  farm to compare WinFaST and FLORIS (series 0, case 0). Both observation time interval  $[t_{o_1}, t_{o_2}]$  and mean wind speed at WT 3 are related to WinFaST; we set  $t_{o_1}$  and  $t_{o_2} = t_{o_1} + 10 \,\mathrm{min}$  as discussed in Sect. 3.2.

#### 4.1 Wind farm yaw angle-offset optimization under different wind directions

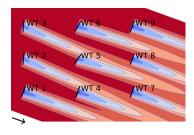

In series 1, we consider a  $6 \times 3$  farm with a wind speed of  $11 \,\mathrm{m\,s^{-1}}$  and wind directions of  $0^{\circ}$ ,  $5^{\circ}$ ,  $10^{\circ}$  and  $20^{\circ}$ . The respective results are presented in Tables 5 and ?? (cases 1 to 3) and Table 5, see also Fig. ?? (9(b) for case 4). In all cases, the improvement of the total power output is between 2% and 17%. In most of these cases, the optimal yaw angles offsets exhaust the given limits of  $\pm 15^{\circ}$ . In case 4 (i.e., wind direction of  $20^{\circ}$ ), the distances between the turbines in the downstream direction are already comparatively high and consequently, the wake influence comparatively low; therefore, the improvement is 2% here, but larger in the other cases.

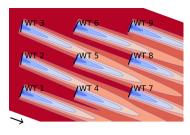

Detailed results of series 1, cases 1 to 3 (see Fig. ?? for case 4) as shown in Table 5. For both yaw controls (baseline or optimized) the power output of each individual turbine is sorted by rows, i.e., WTs 1 to 6 in row 1, WTs 7 to 12 in row 2 and

655 WTs 13 to 18 in row 3, as they often coincide in these examples; exceptions are indicated in brackets, e.g., in case 3, WT 1 outputs 4.15 MW. Further, optimal yaw angles are given sorted by rows (without row 3, as all yaw angles are fixed to 0° there).

— wind direc- row 1 row 2 row 3 row 1 row 2 row 3 row 1 row 2 case tion (in ) (10 )

Detailed results for a  $6 \times 3$  farm, wind speed of  $11 \,\mathrm{m\,s^{-1}}$  and wind direction  $20^\circ$  (series 1, case 4) as shown in Table 5. Subfigure captions specify the wind direction, yaw control (baseline or optimized), and the resulting total power output of the farm.

The main part of the overall run time is the precomputation time, e.g., in series 1 between half an hour and 3 habout 1 to 5 h.

The IPs in our covering approach CA then are all solved in well below 1s by Gurobi, and still within at most 87s 19s by SCIP.

We remind the reader that the precomputations were designed with flexibility in mind, see Sect. 2.2.2, i.e., they can be reused for many cases, see our series 2 for a demonstration. Hence, for the actual optimization process used for control updates, only the solving times of the IPs IP solving times are relevant, which turned out to be so small that we can speak of real-time capable optimization (recall that yaw angles are only updated every 15 min or so in practice, see cf. Sect. 11.2.2). Finally, we see that

the suggested database of precomputated simulation results, see Sect. 2.2.4, is time-consuming to build but enables significant gains through optimization.

670

680

685

690

695

700

The main influence on the precomputation time is the turbines' number in the upstream section; the impact of the allowed number of yaw angles offsets is smaller, cf. Sect. 4.4. The specific upstream sections in series 1 are depicted in Fig. 3; those of cases 1 and 2 (i.e., wind directions  $0^{\circ}$  and  $5^{\circ}$ ) include three turbines and yield precomputation times of about half an hour (cf. Table 5), whereas those of cases 3 and 4 (i.e.,  $10^{\circ}$  and  $20^{\circ}$ ) include four turbines and take about 3+5h. Four turbines (with seven possible yaw angles offsets) result in 512 yaw configurations (i.e., simulations), see the example in Sect. 2.2 and Eq. (5).

As assumptions and discretizations were employed to arrive at our IP model for the WFYP via the covering approach (CA), we *validate* it by comparing the computed power outputs with those obtained from a direct farm simulation with the baseline and optimized yaw configurations. To that end, we examine case 4, but with a TI of 0%, see Fig. ?? for the layout: In the baseline setup, the maximal deviation of any single turbine is 0.02 MW, and 0.05 MW in the optimized one. For the farm's total power in the baseline, our CA results in 63.52 MW (instead of 63.44 MW) and in 64.54 MW (instead of 64.37 MW) for the optimal setting; it indicates that the CA may slightly overestimate the achievable improvement over the baseline setup (1.61% instead of 1.45%). The deviations are limited (in baseline and/or optimization) to WTs {7,12,14,15,...,18} and are due to the size (or shape) of the upstream section, which influences the accuracy of the discretized, section-based WFYP model and therefore is a compromise in terms of accuracy and run time. For example, the covering section (based on upstream section Fig. 3(d)) anchored at WT 7 includes WT 2, but WT 1 is marginally outside, i.e., its influence on WT 7 is not considered; other deviations can be explained analogously. An increase in size of the upstream section would ameliorate the small model inaccuracy, but also significantly increase the precomputation time. Therefore, we accept small inaccuracies in the power output. As the improvements over the baseline are significantly larger than the deviations from full simulation, the optimal solutions of our covering approach will likely still be optimal for a model using increased upstream sections, though suboptimality is technically possible. The IP solver run times themselves indicate that handling larger sections should not pose an issue.

# 4.2 Flexibility Scalability and scalability flexibility of the covering approach to solve the WFYP

In series 2, we examine the influence of the farm size on the solving time of the WFYP, illustrating the practical scalability of our covering approach vis-à-vis the theoretical hardness of the problem (cf. Prop. 2.1). Furthermore, we also conduct an experiment with a mix of active and inactive turbines to show our method's practical flexibility. These experiments also demonstrate the reusability of demonstrate that reusing precomputed simulation results (for section configurations, see Sect. 2.2. In particular, the experimental design for series 2 (i.e., wind direction of  $20^{\circ}$  and speed of  $11 \,\mathrm{m\,s^{-1}}$ ) is the same as in case—), namely series 1, case 4 of series 1 (case 1.4, for short), see Table 5, i.e., we enables our CA to enlarge farms orthogonal to the wind direction (cases 2.1 to 2.4) and to handle cases with deactivated turbines (case 2.5). In particular, we use a wind direction of  $20^{\circ}$  and a speed of  $11 \,\mathrm{m\,s^{-1}}$  to reuse case 1.4 precomputations (originally for a  $6 \times 3$  farm) for  $7 \times 3$ ,  $8 \times 3$  and so on.

For the first experiments, we only change the size of the farm (i.e., 7 to  $9 \times 3$ ) and monitor the workload of the IP solvers  $100 \times 100$  solvers' workload, see Table 6. The optimization consistently improves the farm's total power output by roughly 2%. The impact of the farm size on the IP solving time emphasizes the reflects the theoretical complexity of the WFYP (see Prop. 2.1)

**Table 6.** Data and results to illustrate scalability and complexity of the WFYP (series 2). All cases have a wind direction of  $20^{\circ}$  and a speed of  $11 \,\mathrm{m\,s^{-1}}$  in common. In all cases, the IP optimality gap is 0.00%. (Case 2.1 repeats case 1.4.) We estimate the predicted run time of full enumeration by  $n_{\Gamma}^{n_{\mathrm{WT}} - n_{\mathrm{S}}} \cdot \tau \cdot \frac{1}{4}$ , where  $\tau$  is the run time of one simulation and  $\frac{1}{4}$  is for parallelization effect, see Sect. 2.2.4 for number of combinations.

in practice: the solver SCIP quickly takes an impractically a long time—it could be stopped after 5 min resulting in earlier if a duality gap of, e.g., 1.06% for 9 × 3 was accepted; Gurobi is faster by orders of magnitude remaining well below one minute in all cases considered here, despite an (apparently exponential) increase in run time with the farm size. Thus This illustrates the practical scalability of our CA and, in light of the low yaw sampling rateof, e.g., 15 min (see Sect. 1), our covering approach enables—its suitability for real-time WFYP optimization even for farms with more turbines than explored here. Moreover, we demonstrate the curse of dimensionality of full enumeration via predicted run times, namely in the order of 10<sup>2</sup> to 10<sup>8</sup> y, instead of the 4.5 h precomputation (cf. Table 5).

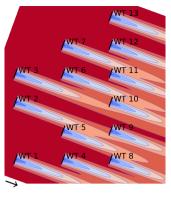

As mentioned before, our covering approach also supports the reuse of precomputed data if some turbines become Furthermore, we handle the case 2.5 with a mix of active and inactive (or do not exist at all), i.e., it allows a flexible reaction to not existing) turbines to show our method's practical flexibility, e.g., to react to a shutdown for maintenanceor an unexpected reason. Case 2.5 illustrates the influence of deactivated turbines on the IP solver behavior and the achievable power gains. Again, we reuse precomputations of case 1.4, cf. Table 5, but now in the setting depicted in Fig. 8, i.e., WTs {2,5,6,9,12} are inactive of comparison to Fig. ??/. The "thinning out" of the farm reduces the solving time of the IP from 86.85s to 0.02s with SGIP, and from 0.35s to below 0.01s using Gurobi. The absolute (relative) improvement of the total power output over the baseline is 0.92MW (1.77%). Thus, the . The WFYP optimization still yields about 2% gain improvement in generated power, while a lower farm density in terms of active turbines namely 1.95%, while the "thinning out" of the farm leads to notably shorter IP solving times: 0.02s (instead of 18.57s) with SCIP and below 0.01s (0.25s) using Gurobi.

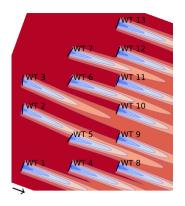

#### 4.3 Impact of different wind speeds

705

720

In series 3, we again consider a  $6 \times 3$  farm and a wind direction of  $20^{\circ}$ , and evaluate WFYP solutions for different wind speeds. The baseline and optimization results of 6, 11 and  $12 \,\mathrm{m\,s^{-1}}$  are reported in Table 7 ( $11 \,\mathrm{m\,s^{-1}}$  repeats case 1.4) and Fig. 9. In all cases, the optimization increases the farm's total power output by about 2%. The the maximum of the precomputation time is about  $3 \,\mathrm{h}$ -5 h and of the IP solving time about  $87 \,\mathrm{s}$  with  $46 \,\mathrm{s}$  (SCIP, ) or under  $1 \,\mathrm{s}$  with (Gurobi-

(a) Baseline: 54.51 MW.

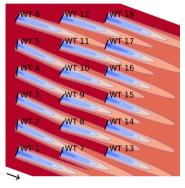

(b) Optimized: 55.57 MW.

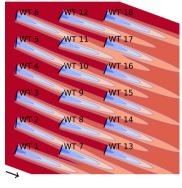

Figure 8. Detailed results for a  $6 \times 3$  farm in which some turbines are inactive (case 2.5 with wind speed of  $11 \,\mathrm{m\,s^{-1}}$  and direction of  $20^\circ$ ). Subfigure captions specify yaw control (baseline or optimized) and the resulting total power output of the farm.

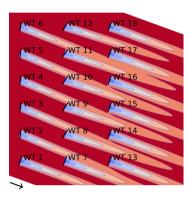

Additional experiments with  $14 \,\mathrm{m \, s^{-1}}$ ). Finally, further experiments provide speeds of  $\{6,7,\ldots,15\}\,\mathrm{m \, s^{-1}}$ : the improvement 725 of the total power is between 0.90% and 2.54% for 6 to  $13 \,\mathrm{m\,s^{-1}}$ , 0.06% for  $14 \,\mathrm{m\,s^{-1}}$ , and  $15 \,\mathrm{m\,s^{-1}}$  show the limit of interesting speeds from power output optimization perspective for the present example: for the 15 m s<sup>-1</sup> (0.00% for 15 m s<sup>-1</sup> (as the baseline already reaches the maximum of 90 MW). For 6 to 14 m s<sup>-1</sup> ) case, all turbines output (almost) their maximum power already in the baseline yaw setting—nevertheless, optimization could still be meaningful if mechanical loads were 730 actually included in the optimization objective. Identifying the corresponding maximum-output wind speed threshold (w. r.t. the baseline) we obtain yaw offsets of the controlled WTs with a similar power output effect, namely  $\pm 15^{\circ}$  for WTs 2 to 6 and  $-10^{\circ}$  or  $-15^{\circ}$  for 8 to 12. This suggests several approaches: the avoidance of many precomputations by identifying the wind speeds' "tipping points" for each wind directionean avoid unnecessary precomputations associated with wind speeds beyond the levels at which optimization can have an effect., i.e., speeds that change the optimal yaw offsets (significantly with 735 regard to the total power), the restricting of admissible yaw offsets around the found values, or the refinement of yaw offsets around the found values (similar to the serial-refine method, see Fleming et al. (2022)). Moving on, in an analysis together with additional experiments, i.e., for wind speeds  $\{6, 8, 10, 11, \dots, 14\}$  m s<sup>-1</sup>, Further, we observe that turbines in a row (apart from those at the farm borders) appear to typically have identical optimal yaw angles offsets (in the same experiment), i.e., the optimal yaw angles for WTs 2 to 5 are the same (except for WT 2 at 8 and 11 m s<sup>-1</sup>), as are those for WTs 8 to 11 (except for WT 11 at 8 m s<sup>-1</sup>). This which is likely due to the grid layout., whereby on the one hand we also have to acknowledge 740 that our number of admissible yaw offsets is not large, on the other hand we refer to Sect. 4.4 for the effect and question of usefulness of a finer discretization. In addition, the optimal yaw angles in the first and second row always differ from 0, except for WTs 1 and 7. So, the result would be the same if we had computed the complete section configuration (i.e., upstream section) without the possibility of 0 in the first and second row; probably, we only need 0 to detect the greedy wind speed 745 threshold. This may provide opportunities toreduce the running times of both precomputations and the resulting IP solution process of sets of all controlled WTs differ from  $0^{\circ}$ : on the one hand this may provide opportunities to reduce the running times

**Table 7.** Data and results to illustrate the impact of wind speeds (series 3). All cases have a  $6 \times 3$  farm layout and a wind direction of  $20^{\circ}$  in common. In all cases, the IP optimality gap is 0.00%. Detailed results are in Fig. 9. (Case 3.2 repeats case 1.4.)

**Figure 9.** Detailed optimization Optimization results for series 3 as shown in Table 7. Subfigure captions specify the wind speed and the farm's total power output. Baseline turbines' power output (in ) is sorted by rows: case 1, row 1 (WTs 1: 0.87; 2: 0.63; 3–6: 0.87), row 2 (7: 0.50; 8–11: 0.68; 12: 0.76), row 3 (13–16: 0.52; 17: 0.41; 18: 0.87)—case 2, row 1 (1: 4.38; 2: 4.40; 3–6: 4.27), row 2 (7: 3.34; 8–11: 3.46; 12: 4.16), row 3 (13–16: 2.10; 17: 2.04; 18: 4.38)—case 3, row 1 (1: 4.91; 2: 4.93; 3–6: 4.94), row 2 (7: 4.55; 8–11: 4.52; 12: 4.84), row 3 (13–16: 2.95; 17: 3.19; 18: 4.91).

of both precomputations and IP solving, on the other hand it might be different for other wind directions, although there are already relatively few wake interactions for the wind direction of  $20^{\circ}$  (which is reflected in the relatively small potential for total power improvement). Finally, the speed of  $15\,\mathrm{m\,s^{-1}}$  is the end of interest from total power optimization perspective for the present example as the improvement is 0.00%. Nevertheless, optimization can still be meaningful if mechanical loads are included: in a further experiment, we weight the tower activity by  $\omega^{(\mathrm{T})} = 100$  and the pitch activity by  $\omega^{(\mathrm{P})}$ , cf. Eq. (13). This results in similar optimal yaw offsets as for 6 to  $14\,\mathrm{m\,s^{-1}}$ , namely  $\pm 15^{\circ}$  for WTs  $\{2,\ldots,5.8,\ldots,12\}$  and  $10^{\circ}$  for WT 6. The total power remains at  $90\,\mathrm{MW}$ , whereas the tower activity decreases to 0.4017 (from 0.4096 in baseline) but the less heavily weighted pitch activity increases to 4.2175 (from 4.1707).

## 755 4.4 Modifying the yaw angle range or offset discretization in terms of range and fineness

In series 4, we deviate from the yaw angle offset discretization ( $[-15^{\circ}, 15^{\circ}]$  in 5° steps, i.e., seven yaw anglesoffsets) used so far: first (, see Table 8 for the results. In case 4.1), we expand the range and we use  $[-40^{\circ}, 40^{\circ}]$ , again in 5° steps (giving i.e., 17 yaw angles), and second (case 4.2), we reconsider  $[-15^{\circ}, 15^{\circ}]$  but with a finer discretization of 2.5° (yielding 13 yaw angles). To this end, we consider a  $6 \times 3$  farm with a wind speed of  $11 \text{ m s}^{-1}$  and a direction of  $5^{\circ}$  offsets, for the setup as in case 4.1 and  $20^{\circ}$  in case 4.2, i.e., we compareto cases 1.2 and 1.4, respectively.

The extension of allowed yaw angles in case 4.1 increases the precomputation time from 0.5 h ((with which we compare cf. Table 5, case 2)to 1.7h, while the number of turbines in the upstream section is unaffected, i.e., three. The IP consists of 1734 variables and 2896 constraints; SGIP needs 0.82s and Gurobi 0.80s to solve it). This increases the precomputation time to 2.6h (compared to 0.7h). As optimal result, all turbines in the first row controlled turbines are set to 30° and each output 3.37 MW, which is significantly lower than in case 1.2 (4.14 MW) due to their higher yaw offset. This enables a similar power output of the second row despite the larger yaw offsets of 35° there, i.e., 2.40 MW (in comparison to 2.45 MW at case 1.2). Finally, this enables a , which enables a significantly increased power output of the downstream-most turbines (with 0°), i.e., 3.49 MW (instead of 1.97 MW 2.9 to 3.1 MW (from 1.7 to 1.9 MW). The total farm output is 55.57 MW (instead of 51.41 MW in case 1.2), i.e., compared to the baseline, the total power output is increased by 26.76% (instead of 17.27% increased to 53.81 MW (from 49.49 MW). The non-use of the new limits of ±40° shows that at the extreme yaw angle offset settings, the power loss at a turbine would exceed the gain at turbines downstream.

Case In case 4.2, we reconsider [-15°,15°] but with 2.5° steps, i.e., 13 offsets, for the setup as in case 1.4 (with which we compare, cf. Table 5), which is particularly interesting for finer discretization (case 4.2) as not all turbines attain extremal yaw angles extreme yaw offsets ±15°. However, all optimal yaw angles in case 4.2 in fact remain the same as in case 1.4, though the finer discretization increases the precomputation time from 2.9h (cf. Table 5, case 4)to 14.6h (of course, still with four turbines in the upstream sectionIndeed, optimal yaw offsets of WTs 8 to 12 are set to -12.5° (from -15° or -10° for WT 12), whereas WTs 2 to 6 remain at 15° (and others at 0°). The IP in case 4.2 consists of 8972 variables and 17950 constraints, for which SCIP needs 58.28h to solve while Gurobi takes only 34.13s. In any caselonger precomputation time of 23.0h (4.5h) is theoretically worthwhile as the total power output is increased further to 70.29MW (from 70.26MW). In practice, it is unnecessary to solve the WFYP with arbitrarily finely discretized yaw angles because of use arbitrarily fine discretizations due to the uncertainty of incident wind conditions, see Stanley et al. (2022) (referenced in Sect. 1.2.1).

We formulated the wind farm yaw problem mathematically, established its computational complexity and developed a covering approach, which exploits that the farm can be covered by patterns based on a smaller, precomputable so-called upstream section, in the form of integer programming to solve it with integer programming faster. Building on a number of simulation results that can be precomputed at any time before the need for yaw control arises, the method is efficient in practice in spite of the problem's strong  $\mathcal{NP}$ -hardness and inapproximability. In particular, we fully expect even very long precomputation times (e.g.,

**Table 8.** Data and results if yaw offset range or discretization are changed (series 4). All cases consider a  $6 \times 3$  farm with a wind speed of  $11 \,\mathrm{m\,s^{-1}}$ . In all cases, the IP optimality gap is 0.00%.

months) to be acceptable as the simulations can easily be run for various wind scenarios while the farm is not yet operational. Given the envisioned database, our covering approach CA efficiently delivers optimal yaw control using a state-of-the-art IP solver like Gurobi. The solution is even globally optimal under some mild assumptions as discussed in Sect. 1.2.1., like discretized yaw offsets, chosen size of so-called upstream section, and homogeneous layout structure. In addition, it enables tackling even farms with many turbines. We demonstrated the performance of our approach with several proof-of-concept examples that illustrate its effectiveness, flexibility and scalability, particularly through the reuse of precomputations if we enlarge the farm orthogonally to the wind direction or deactivate turbines. On the other hand, the enlargement in wind direction increases the upstream section and therefore the number of turbines inside, which mainly increases the precomputation time. As our covering approach CA is a superordinate model, the simulation is interchangeable. The utilized, e.g., to use FLORIS simulation as shown that does not utilize dynamic models (for wakes and turbines) possibly made the precomputation more expensive than necessary when only focusing on the power output. Presuming that the influence of a substitution on the resulting optimal yaw angles is small, the precomputation time would decrease considerably... Finally, it might be helpful to solve the WFYP for the associated farms by our covering approach CA for a variety of wind directions and speeds to recognize structures whose exploitation reduces the computational effort in precomputation or simplifies the WFYP itself. Solving the WFYP for the associated farms by covering approach CA in all considered wind scenarios should provide knowledge to reduce the computational effort.

Code and data availability. For simulation, we used the MATLAB software package WinFaST. This company-internal software is not publicly available, but based on known methods, as described in Sect. 3.1. As our own optimization framework is presently entwined with WinFaST and hence not a stand-alone program, we have not made it publicly available at this time. Nevertheless, in Sect. 2, we provide a detailed description of the problem, the novel CA, integration/utilization of simulation results and the WFYP formulation as an IP. As data to supplement the article, we provide the IPs (1p-files) and corresponding solver log files for each case of our series of experiments. The data is available at Zenodo: https://doi.org/10.5281/zenodo.14900916.

## 810 Appendix A: Complexity of the wind farm yaw problem

815

825

830

This section addresses the computational complexity of the wind farm yaw problem from a theoretical viewpoint; we assume a basic knowledge of mathematical complexity theory and refer to Garey and Johnson (1979) for a detailed introduction. Using the basic black-box IP formulation (2) to (4) of the wind farm yaw problem (WFYP; WFYP (cf. Sect. ??2.1), we show that the WFYP is strongly  $\mathcal{NP}$ -hard (Theorem A.3) and even hard to approximate (Corollary A.4). These two results together yield Proposition 2.1 as stated in Sect. ???.

2.1. We use the well-known strongly  $\mathcal{NP}$ -complete Hamiltonian Circuit (HC) problem, see, e.g., (Garey and Johnson, 1979, problem GT37), for our proof.

**Definition A.1** (Hamiltonian Circuit Problem (HCP)). Let an undirected graph G = (V, E) on n vertices,  $V := \{v_1, \ldots, v_n\}$ , be given. Does G contain a Hamiltonian circuit, i.e., a subset of edges  $\mathcal{H} = \{\{v_{\pi(1)}, v_{\pi(2)}\}, \{v_{\pi(2)}, v_{\pi(3)}\}, \ldots, \{v_{\pi(n-1)}, v_{\pi(n)}\}, \{v_{\pi(n)}, v_{\pi(1)}\}\} \subset E$  for a permutation  $\langle v_{\pi(1)}, v_{\pi(2)}, \ldots, v_{\pi(n)} \rangle$  of V?

For clarity, we also explicitly state the decision version of the WFYP problem.

**Definition A.2** (WFYP decision version (WFYP-DEC)). Let the index set T of wind turbines in a wind-farm, its layout  $\mathcal{L}$ , the index set  $\Gamma_i := \{1, \dots, n_{\Gamma, i}\}$  of admissible yaw angles offsets for each turbine  $i \in T$ , the WFYP objective function  $f_{\omega}^{\Sigma}$  as defined for (the (its (black-box) IP formulation of) the WFYP, and a number  $F \in \mathbb{R}$  be given. Does there exist a feasible yaw configuration for the given farm (i.e., exactly one yaw angle offset per turbine) such that, for the associated binary yaw angle offset assignment vector x,  $f_{\omega}^{\Sigma}(x) \geq F$ ?

Recall that the assignment vector  $x \in \{0,1\}^{n_{\Gamma_1}+\dots+n_{\Gamma_n}}$ , with the entry in position  $\sum_{\ell=1}^{i-1} n_{\Gamma_\ell} + j$  being denoted by  $x_{i,j}$  and having value 1 if and only if the i-th turbine is set to the j-th yaw angle offset from among the respective admissible set  $\Gamma_i$ . In the following, we will also use some additional notation: We we denote the so-called triangular numbers by  $\Delta_n := {n+1 \choose 2} = \frac{n^2+n}{2}$  and abbreviate the set of the first N triangular numbers as  $\Delta(N) := \{\Delta_1, \Delta_2, \dots, \Delta_N\}$ . Also, for a natural number  $n \in \mathbb{N} = \mathbb{Z}_{>0}$ , we denote, and write  $[n] := \{1, 2, \dots, n\}$  for  $n \in \mathbb{N}$ .

We are now prepared to prove the  $\mathcal{NP}$ -hardness and inapproximability of the WFYP(-DEC).

# **Theorem A.3.** The wind farm yaw problem WFYP is strongly $\mathcal{NP}$ -hard.

*Proof.* We show hardness for the decision version WFYP-DEC, which directly implies hardness for the optimization version (WFYP, as defined in Sect. 2), cf. Garey and Johnson (1979). To that end, we reduce from the strongly  $\mathcal{NP}$ -complete HCP. Let G = (V, E) be an arbitrary HCP instance, and denote n = |V|. We can assume w.l.o.g. that  $n \ge 2$ , every vertex has degree at least 2, and that G consists of a single connected component (otherwise, the answer to the HCP is trivially "no"). We construct an instance  $(T, \mathcal{L}, \{\Gamma_i\}_{i \in T}, f_\omega^{\Sigma}, F)$  of the WFYP-DEC as follows:

We set the number of turbines to  $n_{\rm WT} := \Delta_n + 1$  and identify the turbines by their index, i.e.,  $T := [\Delta_n + 1]$ . The turbines are arranged in a triangle-like layout  $\mathcal{L}$  (on a regular grid)<sup>3</sup> defined by the following "row" sets:

$$R_1 := \{\Delta_1\} = \{1\},$$
  $R_2 := \{\Delta_2, 2\},$   $R_3 := \{\Delta_3, 5, 4\},$   $\vdots$  ...,  $R_n := \{\Delta_n, \Delta_n - 1, ..., \Delta_{n-1} + 1\},$   $R_{n+1} := \{\Delta_n + 1\}.$ 

Furthermore, each turbine  $i \in T$  is given the same set of admissible yaw  $\frac{\text{angles}}{\text{angles}} = \frac{1}{1} \sum_{i=1}^{n} \frac{1}{i} = n$  for all  $i \in T$ . Finally, we set F := n, and define the terms  $f_{\omega,i,j}(x)$  of the simulation function  $f_{\omega}^{\Sigma}(x) := \sum_{i=1}^{n_{\text{WT}}} \sum_{j=1}^{n_{\Gamma,i}} f_{\omega,i,j}(x) x_{i,j} = \sum_{i=1}^{n_{\Gamma,i}} f_{\omega,i,j}(x) x_{i,j}$  as

$$f_{\omega,i,j}(x) := \begin{cases} 0 & \text{if } i = 1 (= \Delta_1) \text{ and } j \in [n], \\ 1 & \text{if, for some } k \in [n], \ i = \Delta_k > 1, \ x_{\Delta_{k-1},\ell} = 1 \text{ for some } \ell \text{ such that } \{v_\ell, v_j\} \in E, \\ & \text{and } j \in [n] \setminus \left\{q \in [n] : \sum_{s \in R_{k-1}} x_{s,q} > 0\right\} \\ 0 & \text{if, for some } k \in [n], \ i \in R_k \setminus \left(\Delta(n) \cup \left\{\Delta_n + 1\right\}\right) \text{ and } x_{i-k+1,j} = 1, \\ 1 & \text{if } i = \Delta_n + 1, \ x_{\Delta_{n-1}+1,j} = 1, \text{ and } \{v_j, v_\ell\} \in E \text{ for } j \text{ such that } x_{\Delta_n,\ell} = 1, \\ 1 - n & \text{otherwise.} \end{cases}$$

For a (feasible) overall yaw configuration of the farm as determined by x, the components  $f_{\omega,i,j}(x)$  of  $f_{\omega}^{\Sigma}(x)$  specify the objective contribution (or profit, for short) incurred by turbine i using the yaw angle offset (indexed by) j. Specifically, the first case in Eq. (A1) defines a zero profit for any arbitrary yaw angle offset assignment to the first turbine. The second case then yields a profit of 1 if a turbine that corresponds to a triangular number  $\Delta_k > 1$  has been assigned (according to the input yaw configuration x) a yaw angle offset j that was not chosen for any turbine in the previous row (set k0, and k1 and k2 are assigned yaw angles offset k2 chosen for turbine k3, the edge k4 chosen for turbine k4 chosen for turbine k5 and k6. (For example, supposing turbines k6 and the k7 and k8 are assigned yaw angles offsets k8 and k9 are setting for turbine k9 yields a profit of 1 only if k9. The third case means that using yaw angleoffset k9 for any turbine in the previous row, which in this case translates to k7. The third case means that using yaw angleoffset k9 for any turbine k9 for any turbine k9. The third case means that using yaw angleoffset k9 for any turbine k9 for any turbine k9. The third case means that using yaw angleoffset k9 for any turbine k9 for any turbine k9. The third case translates to k9 for any turbine k9 for any turbine k9. The third case that the turbine is k9 for any turbine k9. The penultimate case yields a unit profit in the special case that the turbine is k9 for k9 being the yaw angleoffset k9 is also used by turbine k9. Finally, the last case sets the function value to k9 for all other configurations. Fig. A1 illustrates the dependency structure of the function.

850

855

860

This completes the construction of a WFYP-DEC instance  $(T, \mathcal{L}, \{\Gamma_i\}_{i \in T}, f_\omega^\Sigma, F)$  from the input HCP instance G. Note that the reduction (dimensions, all arithmetic operations and constructed numbers) clearly requires only polynomial time and

<sup>&</sup>lt;sup>3</sup>In fact, the precise layout does not matter, since all implications regarding the resulting wake influences are "hidden" in the black-box function (i.e., in the practical application, handled within the simulation framework); the same holds for the exogenously given (arbitrary but fixed) wind speed and direction.

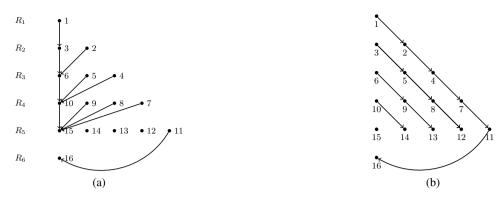

Figure A1. Visualization of black-box function dependencies in the reduction from HCP to WFYP-DEC, exemplified for graph with n=5 nodes. Arcs in (a) represent the dependencies in the constructed farm (i.e., which turbines bear influence on which others) for the first two cases in Eq. (A1), while arcs in (b) represent those for the remaining cases in Eq. (A1). Note that actual function values depend on input x.

space with respect to the size of the input; in particular, the objective function can be evaluated in  $\mathcal{O}(n^3)$ , since  $|T| = n_{\text{WT}} = \Delta_n + 1 \le n^2$  and  $n_{\Gamma i} = n$  for all  $i \in T$ . (In fact, it can easily be seen that our reduction allows the "strongly" part of  $\mathcal{NP}$ -hardness to carry over from the HCP, cf. Garey and Johnson (1979).)

It remains to show that the given graph contains a Hamiltonian circuit  $\mathcal{R}$  if and only if the constructed WFYP-DEC instance  $(T, \mathcal{L}, \{\Gamma_i\}_{i \in T}, f_\omega^\Sigma, F)$  admits a solution x with objective value  $f_\omega^\Sigma(x) \geq F = n$ .

To that end, first assume that  $\hat{x} \in \{0,1\}^{(\Delta_n+1)n}$  is a feasible solution for WFYP-DEC (so every turbine is assigned exactly one yaw angleoffset) with objective value  $f_{\omega}^{\Sigma}(\hat{x}) \geq F$ . Since by construction, only n turbine yaw settings can possibly incur a profit of 1 each (and all others at most zero),  $f_{\omega}^{\Sigma}(\hat{x}) = F = n$  does in fact hold, which also implies that the last case in the function definition (A1) never occurs (since otherwise,  $f_{\omega}^{\Sigma}(\hat{x}) \leq 1 - n + n = 1 < n$  would hold—a contradiction). In particular, tracing the functional dependencies with regard to which yaw angle offset assignments incur which costs for subsequent turbines (in the "cascading" row sets), we can conclude that no yaw angle offset is chosen twice among the turbines  $1, \Delta_2, \Delta_3, \ldots, \Delta_n$ . Moreover, due to the first two cases in Eq. (A1) (and since  $\hat{x}$  represents a feasible yaw configuration), and because every turbine has the same set of n admissible yaw anglesoffsets, it holds that each yaw angle offset is chosen exactly once for this set  $\{1,\Delta_2,\Delta_3,\ldots,\Delta_n\}$  of turbines. Furthermore, note that by definition, any yaw setting j for turbines  $i=\Delta_{k-1}+1,\ k=2,\ldots,n$ , incurs a profit of either 1-n or 0, but that since  $f_{\omega}^{\Sigma}(\hat{x})=n$ , the respective settings prescribed by  $\hat{x}$  in fact all yield zero profit. Thus, these costs necessarily arise from the third case in Eq. (A1), which means that turbines  $\Delta_1+1,\Delta_2+1,\ldots,\Delta_{n-1}+1$  all have the same yaw angle offset as turbine 1. Consequently, by the fourth case in the definition, the yaw configurations chosen for turbines  $\Delta_1=1$  and  $\Delta_n+1$  are also identical.

We can now construct a Hamiltonian circuit in G from this WFYP solution  $\hat{x}$ : Starting starting at vertex  $v_{p_1} \in V$ , where  $p_1 \in [n]$  is the yaw angle offset chosen for turbine  $\Delta_1 = 1$ , we visit the other n-1 nodes in the order prescribed by the yaw angles offsets selected for the turbines  $\Delta_1, \ldots, \Delta_n$ , and finally moving from the last node back to  $v_{p_1}$ . Indeed, this traversal produces the tour  $\hat{\mathcal{R}} = \{\{v_{p_1}, v_{p_2}\}, \{v_{p_2}, v_{p_3}\}, \ldots, \{v_{p_{n-1}}, v_{p_n}\}, \{v_{p_n}, v_{p_1}\}\}$ , which shows that a "yes" answer for the constructed WFYP-DEC instance yields a "yes" answer for the original HCP instance.

885

For the converse direction, let a circuit  $\hat{\mathcal{R}} = \{\{v_{\pi(1)}, v_{\pi(2)}\}, \dots, \{v_{\pi(n-1)}, v_{\pi(n)}\}, \{v_{\pi(n)}, v_{\pi(1)}\}\}$  be a "yes" certificate for the given HCP instance G. Then, we can derive a solution  $\hat{x}$  with cost  $f_{\omega}^{\Sigma}(\hat{x}) = n = F$  for the constructed WFYP-DEC instance from  $\hat{\mathcal{R}}$  as follows: For for turbines  $1, \Delta_2, \Delta_3, \dots, \Delta_n, \Delta_n + 1$ , we respectively select the yaw angles offsets corresponding to the indices of the vertices in the order prescribed by the tour  $\hat{\mathcal{R}}$ , starting (and ending) at  $v_{p_1} = v_{\pi(q)}$  for some  $q \in [n]$ , i.e., we set  $\hat{x}_{1,\pi(q+1)} = \hat{x}_{\Delta_2,\pi(q+2)} = \dots = \hat{x}_{\Delta_n,\pi(q+n)} = \hat{x}_{\Delta_n+1,\pi(q)} = 1$  (yielding total profit  $0+n\cdot 1=n$ ) while the entries corresponding to these turbines and the respective remaining yaw angles offsets are all set to zero. For the remaining turbines, we pick yaw angles offset that incur no negative profits, i.e., for any  $k=2,\dots,n$ , turbine  $i\in R_k\setminus(\Delta(n)\cup\{\Delta_n+1\})$  is assigned the same yaw angle offset as turbine i-k+1, respectively, all with profit 0. Since this way, every turbine is assigned exactly one yaw angleoffset,  $\hat{x}$  indeed describes a feasible yaw configuration and by construction, its objective function value corresponds to  $f_{\omega}^{\Sigma}(\hat{x}) = n = F$ . This shows that the constructed WFYP-DEC instance also has a "yes" answer, which completes the proof.  $\square$ 

We remark that the above construction could easily be adapted so that only non-negative terms can occur in the objective<sup>4</sup>, as would be the case in our application when focusing solely on power generation. Note also that, due to the generality of the black-box function  $f_{\omega}^{\Sigma}$  in WFYP-DEC it is unclear whether one could always find a *rational* certificate of an arbitrary "yes" instance, so containment in the complexity class  $\mathcal{NP}$  (and thus,  $\mathcal{NP}$ -completeness) remains open. However, more importantly, we can slightly modify the proof of Theorem A.3 to obtain the following inapproximability result.

**Corollary A.4.** There is no polynomial-time  $\alpha$ -approximation algorithm for WFYP, for any  $\alpha \leq 1$ , unless  $\mathcal{P} = \mathcal{NP}$ .

900

905

*Proof.* Revisiting the construction from the proof of Theorem A.3 we modify the function values in Eq. (A1) to 0,  $\delta$ ,  $\delta$ ,  $\delta$  and  $-\varepsilon$  for the five cases, respectively, which then establishes the existence of a Hamiltonian circuit in G if and only if there is a feasible WFYP solution with value  $\frac{1}{2}(n^2+n-2)\delta$ . Let  $\varepsilon:=\frac{1}{2}(n^2+n-4)$  and  $\delta:=4(\Delta_n+1)\varepsilon=n^4-3n^2+6n-8$ . Then, if the original HCP instance was a "yes"-instance, any non-optimal solution of the constructed WFYP instance has solution value at most  $\frac{1}{2}(n^2+n-4)\delta-\varepsilon$ . Now suppose there exists a polynomial-time  $\alpha$ -approximation algorithm for some arbitrary  $1/(n^2+n-1)<\alpha\le 1$ . Since any non-optimal solution (for a WFYP instance constructed from a HCP "yes"-instance) has value at most  $\frac{1}{2}(n^2+n-4)\delta-\varepsilon$ , but the  $\alpha$ -approximation algorithm outputs a solution with value at least  $\alpha\cdot(n^2+n-2)\delta/2$ , it can only be the case that the solution computed by the algorithm is non-optimal if

$$910 \quad \alpha \left(\frac{n^2+n-2}{2}\right) \delta \leq \left(\frac{n^2+n-4}{2}\right) \delta - \varepsilon \quad \Leftrightarrow \quad \alpha \leq \frac{n^2+n-4}{n^2+n-2} - \frac{2\varepsilon}{n^2+n-2} = 1 - \frac{2}{n^2+n-2} - \left(1 - \frac{2}{n^2+n-2}\right) = 0,$$

which contradicts the prerequisite  $\alpha > 1/(n^2+n-2) > 0$ . Thus, the  $\alpha$ -approximation algorithm does, in fact, always yield an (optimal) solution of value  $\alpha(n^2+n-2)\delta/2$  if and only if the input HCP instance was a "yes"-instance. It could therefore be used to decide the existence of a Hamiltonian circuit in polynomial time, contradicting  $\mathcal{NP}$ -hardness of the HCP. To see that this implies that no polynomial-time  $\alpha$ -approximation can exists exist (provided  $\mathcal{P} \neq \mathcal{NP}$ ) for any  $0 < \alpha \le 1$ , it suffices to observe that  $1/(n^2+n-2) \to 0$  as  $n \to \infty$ .

<sup>4</sup>To that end, we can replace the profit for the third and fifth case in Eq. (A1) by 
$$\varepsilon > 0$$
 and 0, respectively. Then, the construction instance has a solution of value  $n + \varepsilon (n^2 - n - 2)/2$  if and only if G is Hamiltonian.

<sup>&</sup>lt;sup>5</sup>The same upper bound holds for the optimal value in case of HCP "no"-instances. Moreover, it is easy to see that  $f_{\omega}^{\Sigma}(x) > 0$  for any non-trivial feasible x, i.e., any x that yields profit  $\delta$  for at least one index pair (i,j), which is trivially always achievable, so no reasonable algorithm would ever yield  $f_{\omega}^{\Sigma}(x) \leq 0$ .

Author contributions. CK and SS deliberated the overarching research goals, wrote the corresponding project proposal, were responsible for the funding acquisition, and had the idea to tackle the wind farm yaw problem by discretization. FBü formulated the integer program of the covering approach, wrote the source code, and designed as well as performed the experiments. FBü and AT deliberated the experimental design and result analysis. FBe and AT construed and wrote the  $\mathcal{NP}$ -hardness and inapproximability proofs. FBe, FBü and AT wrote and revised the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

920
