Abstract. The interplay of momentum surrounding wind farms significantly influences wake recovery, affecting the speed at which wakes return to their free-stream velocities. Under stable atmospheric conditions, wind farm wakes can extend over considerable distances, leading to sustained vertical momentum flux downstream, with variations observed throughout the diurnal cycle. Particularly in regions such as the US Great Plains, stable conditions can induce low-level jets (LLJs), impacting wind farm performance and power output. This study examines the implications of wake recovery using long-term observations of vertical momentum flux profiles across diverse atmospheric conditions. In these observations, several key findings were observed, such as a) LLJ heights are altered downstream of a wind farm, especially when the LLJs are below 250 m above ground level, b) a notable impact of LLJ height on wake recovery is observed using momentum flux profiles at upwind and downwind location, wherein LLJs between 250 m and 500 m above ground level resulted in larger momentum transfer within the wake (i.e., smaller velocity deficit) compared to LLJs below 250 m above ground level, c) largest momentum flux variability is observed during stable atmospheric conditions, with non-negligible variability observed during neutral and unstable atmospheric conditions, d) detection of wake effects is almost always observed throughout the atmospheric boundary layer height, and finally e) enhancement of wake recovery is observed in the presence of propagating gravity waves. These insights deepen our understanding of the intricate dynamics governing wake recovery in wind farms, advancing efforts to model and predict their behaviour across varying atmospheric contexts. In addition, the performance of large-eddy simulation-based semi-empirical internal boundary layer height model estimates incorporating real-world atmospheric and turbine inputs was evaluated using observations during LLJ conditions.

1 Introduction

25 Wind turbine wakes, i.e., velocity deficits due to extraction of the kinetic energy from an operating wind turbine, are observed to extend several kilometres during stable atmospheric conditions both onshore and offshore (Hirth et al., 2012; Banta et al., 2015; Krishnamurthy et al., 2017; Fernando et al., 2019; Ahsbahs et al., 2020; Zhan et al., 2020). Wind farm wakes from a large cluster of wind turbines in mesoscale model simulations and offshore observations can reach over 50 km downwind under stable atmospheric conditions (Platis et al., 2018; Lundquist et al., 2019, Schneemann et al., 2020). Large-eddy
30 simulations of large wind farms also show that wind farm wakes can alter the surface momentum and heat fluxes (Calaf et al.,

2011). Wind farm wakes are known to impact the local meteorological conditions by, for instance, increasing or decreasing the temperature and enhancing turbulence downwind of a wind farm (Baidya Roy et al., 2004; Smith et al., 2013; Siedersleben et al., 2018; Miller and Keith, 2018, Bodini et al., 2021), although the intensity of the impact depends on atmospheric stability, local atmospheric processes, orientation of the wind farms, downwind distance, number and operative regimes of wind
35 turbines, etc.

In operational wind farms, intra-farm wakes can result in significant power losses and it is important to understand the dissipation of wakes within a wind farm. The effect of a wind turbine is to decrease the mean velocity and increase the turbulent kinetic energy above the rotor layer (the layer from the bottom of the wind turbine blade tip to the top of the blade
40 tip, VerHulst and Meneveau, 2014). The turbulent transport term in a steady-state filtered-energy equation includes the entrainment of the mean momentum due to turbulence and the entrainment of the turbulent kinetic energy due to fluctuating velocities (Allaerts and Meyers, 2017). Downwind of a wind farm, the recovery of a wind turbine wake within the rotor layer largely occurs due to enhanced entrainment of the vertical momentum flux from the boundary layer (Abkar and Porte-Agel, 2013; Yang et al., 2014; VerHulst and Meneveau, 2014; Abkar and Porte-Agel, 2014; Lu and Porte-Agel, 2015). The maximum
45 energy produced by a large (>100MW) land-based wind farm is then constrained by the momentum flux between the surrounding atmosphere and the flow within the wind farm. Therefore, measuring the entrainment of the mean momentum due to turbulence upwind and downwind of an operational wind farm can provide insight into the momentum balance of wakes within a wind farm. The momentum balance can be a function of various locally observed atmospheric phenomena, such as low-level jets (LLJ), gravity waves, high shear/veer events etc. Atmospheric stability is known to impact the extent of wake
50 propagation downstream (Hansen et al., 2012, Barthelmie et al., 2012, Hirth et al., 2012, Smith et al. 2013, Krishnamurthy et al., 2017, Lundquist et al., 2019). In conjunction with some of the local atmospheric features, the transfer of momentum within and outside the surrounding wind farm can show drastic spatial and temporal heterogeneity.

Today's wind turbines operate within the lowest 300 m of the atmospheric boundary layer (ABL), and in offshore or stable atmospheric conditions the ABL can be lower than 300 m (Shaw et al., 2022). Although wind farms operate within 300
55 m above ground level, their impacts can be observed through the entire depth of the boundary layer. Therefore, to accurately assess such impacts, observations of mean and turbulent characteristics of wind and temperature should be extended up to the top of the ABL. Remote sensing instruments, such as Doppler lidars, are capable of estimating the mean winds within the ABL (Frehlich, 1994, Frehlich, 2001, Peña et al., 2009, Krishnamurthy et al., 2013, Newsom and Krishnamurthy, 2021) as well as turbulence with accuracy comparable to sonic anemometers, which are considered a standard for atmospheric turbulence
60 measurements (Frehlich and Cornman, 2001, Frehlich et al., 2006, Banakh and Smalikho, 1997, Krishnamurthy et al., 2012, Sathe et al., 2015, Bonin et al., 2017, Wildmann et al., 2019). Certain observational studies have validated the propagation of wakes for long distances downwind (more than 20 rotor diameters [RDs]), using targeted long-range scanning radar measurements (Hirth et al., 2012; Ahsbabs et al., 2020), satellite-based radar observations (Djath et al., 2018) and airborne observations (Lampert et al., 2020). But other observations have also shown that wake deficits are small at larger RDs (~26

65 RDs) downstream of a multimegawatt wind farm (Smith et al., 2013). As wake extent grows laterally downwind of a wind
farm, measuring velocity deficits at larger downwind distances can get very challenging, due to small deficits. Therefore,
assessing the impact of wakes purely based on wind speed and turbulence intensity estimates at targeted observational
70 locations, would not provide a good representation of wake dissipation. Large-eddy simulations have previously shown
momentum deficit estimates within and above the wind farm rotor layer at large downwind distances (Stevens., 2016, Gadde
and Stevens, 2021) and provide more realistic information about the influence of wind farm wakes on the atmospheric
boundary layer. Therefore, accurately measuring momentum deficits at various downwind distances of a wind farm, rather
than just mean winds and turbulence intensity profiles, might provide a better assessment of wind farm wakes. Recent studies
have focused on observing momentum flux variability around a wind farm using in-situ observations on an aircraft (Syed et
al., 2023), but there has not been a study, as per the authors knowledge, looking at any systematic and statistically significant
75 trends in vertical momentum flux profiles under a variety of atmospheric conditions surrounding an operational wind farm.
Therefore, it would be essential to know under what atmospheric conditions wakes recover faster, thereby reducing the impact
on downwind wind farms or turbines for optimal siting of wind farms/turbines and power production estimates.

Gravity waves and atmospheric bores are ubiquitous in the SGP region (Carbone et al., 1990, Davis et al., 2003,
Geerts et al., 2017). Although most frequently observed during nocturnal and stable atmospheric conditions, they vary
80 significantly in their period and amplitude. These nocturnal convective systems typically accompany high winds, intense rain
and/or hail and sometimes tornadoes (Maddox, 1980). The forecast skill of such atmospheric events is relatively low in both
numerical weather prediction models and coarse-grid climate models (Davis et al., 2003, Pritchard et al., 2011). They also
typically include a LLJ within the atmospheric boundary layer, which supports the moisture transport above the stable
boundary layer over the SGP (Berg et al., 2015, Krishnamurthy et al., 2021a). Primarily gravity waves create wave-like
85 oscillations in the atmosphere due to the presence of a density gradient and bore disturbances are shown to have a significant
upward displacement of wind within the troposphere (Rottman and Simpson, 1989, Parsons et al., 2019). Such wave-like
disturbances when reaching the surface, can create undulations in the mean winds depending on the period and wavelength of
the wave. Mountain waves have previously been known to impact the power production of a wind farm (Draxl et al., 2021)
but the impact of propagating gravity waves on wake recovery is not very well understood.

90 Wind farms create a step change in surface roughness and when the atmospheric boundary layer height (δ) is larger
than the surface momentum roughness (z_{0m}), an internal boundary layer (δ_{IBL}) is developed in the region downstream of the
surface discontinuity (Elliot 1958, Taylor 1969, Calaf et al., 2013, Stevens et al., 2016, Krishnamurthy et al., 2023). The
boundary layer flow is observed to adjust to this new surface condition and grows with downstream distance (x). The growth
of the internal boundary layer is a function of mean wind, thermal stratification or atmospheric stability, inversion height of
95 the ABL, and surface turbulence characteristics. In the presence of a wind farm, the growth of an internal boundary layer is
also a function of the mean wind turbine spacing and characteristics of the wind turbine performance (Calaf et al., 2013,
Stevens 2016, Stevens and Meneveau, 2017). The momentum flux into a wind farm replenishes the wake of the wind farm
and the height of the internal boundary layer can reach up to δ . During stable atmospheric conditions, δ_{IBL} will grow to reach

100 δ within a short distance from the leading edge of a wind farm, resulting in a fully developed IBL. While most of the existing studies have been based on high-resolution models, limited long-term observations of δ_{IBL} growth are available in the literature. Syed et al., 2023 showed spatial variability of momentum flux measurements from in-situ sensors onboard an aircraft upstream, above, and downstream of a wind farm, but did not provide a vertical profile up to the boundary layer. Therefore, estimating profiles of momentum flux up to the boundary layer depth can provide insights into the impact of internal boundary layers on wind farm dynamics.

105 Dimensional arguments show that at far field, large x , as equilibrium conditions prevail, i.e., $u_*^d/u_*^u = \mathcal{F}_1(z_0^u/z_0^d)$, where u_*^d and z_0^d are downwind friction velocity and roughness length, \mathcal{F}_1 is an unknown function, while the superscripts u , refers to upwind estimates (Krishnamurthy et al., 2023). In the presence of a wind farm, the model presented in Calaf et al., 2010 assumes two constant stress levels, above ($u_{*,hi}$) and below ($u_{*,lo}$) the wind turbine, with the difference between those momentum layers given as

$$110 \quad u_{*,hi}^2 = u_{*,lo}^2 + \frac{1}{2} c_{ft} (\langle \bar{u} \rangle_{z_h})^2, \quad (1)$$

where $\langle \bar{u} \rangle_{z_h}$ is the horizontally and time averaged velocity at hub-height, $c_{ft} = \frac{\pi C_T}{(4S_x S_y)}$, C_T is the turbine coefficient of thrust, and lateral and transverse spacing between the wind turbines is given by S_x and S_y . Using a logarithmic wind profile 115 formulation ($U(z) = u_* \ln(z/z_0)/\kappa$), where κ is von Karman constant (0.4), a relationship for wind turbine roughness height of the wind farm ($z_{0,hi}$) can be estimated (Stevens 2016). Thereby, the growth of the internal boundary layer due to a wind farm can be estimated using (Willingham et al., 2014)

$$120 \quad \frac{\delta_{IBL}(x)}{z_{0,hi}} = \frac{\delta_{IBL}(0)}{z_{0,hi}} + C_1 \left(\frac{x}{z_{0,hi}} \right)^{4/5}, \quad (2)$$

where, x is the downwind distance, $\delta_{IBL}(0)$ is the internal boundary layer height of the wind turbine rotor top at the first row of the wind farm (equal to the wind turbine blade upper tip height), $z_{0,hi}$ is the surface roughness due to the presence of a wind farm, and C_1 is a growth constant (0.28) estimated from large-eddy simulation models (Calaf et al., 2010, Stevens, 2016). The wind farm surface roughness is a function of the upwind surface friction velocity, wind turbine and farm parameters, and 125 inflow mean wind conditions within the wind turbine rotor layer. Existing large-eddy simulations estimates of internal boundary layers have typically used idealized conditions while real-world atmospheric conditions estimate of IBL might differ considerably due to competing atmospheric conditions. Therefore, observations of internal boundary layer growth are important to understand the impact of wind farms on the ABL and thereby the momentum balance surrounding a wind farm and associated wake replenishment.

130 In this paper we investigate the wake recovery of a wind farm, by investigating the momentum balance (primarily
mean streamwise momentum flux $[(u'w')]$) surrounding an operational wind farm near the Atmospheric Radiation
Measurement (ARM) program Southern Great Plains (SGP) sites in Oklahoma during various site-specific atmospheric
phenomena. Momentum flux profiles from scanning Doppler lidars and surface sonic anemometers are estimated for both
upwind and downwind locations relative to the wind farm. Information about the field campaign and site characteristics are
135 given in Section 2. Momentum flux profiles upwind and downwind of an operational wind farm during site-specific
atmospheric conditions are discussed in Section 3. Wind farm IBL measurements, comparison of data with theoretical models
are given in Section 4 and results are summarized in Section 5.

2 Field campaign and site characteristics

140 Oklahoma ranks third in the United States for installed wind capacity, providing over 37,418 GWh of electricity in 2022.
The state generated approximately 44% of its electricity from wind energy in 2022, the third highest in the country, and
provided enough electricity to power millions of U.S. homes. The landscape and topographic flows around SGP are relatively
simple compared to complex terrain sites with low wind speed interannual variability ($< 3\%$) and therefore are favored by
145 wind farm developers (Krishnamurthy et al., 2021a).

To investigate the interaction between wind farms and the ABL and improve our understanding of wind turbine and wind
farm wake effects, the U.S. Department of Energy (DOE) funded a field campaign, American WAKE experiemeNt
(AWAKEN), within and adjacent to King Plains wind farm near Enid, Oklahoma (Debnath et al., 2023, Moriarty et al., 2023).
Figure 1 shows the domain of the AWAKEN field experiment, various locations with instruments deployed, and operational
150 wind turbines within the domain. Several remote sensing and in-situ sensors were deployed, please see Moriarty et al., 2024
for additional details of the site setup and layout.

In this article, data from primarily two instrumented sites are used for data analysis. Site A2 is the inflow site and site H
the outflow site to the King Plains wind farm during southerly wind directions. Figure 1 shows a picture of both the sites and
various instruments deployed. Site A2 was instrumented with a Scanning Doppler lidar, short-range vertical profiling lidar,
155 surface sonic anemometer, and a surface meteorological station, while site H had a scanning Doppler lidar, microwave
radiometer, and two disdrometers. Both the scanning lidars were oriented close to North, like the sonic anemometers. Azimuth
and elevation offsets for the scanning lidars were identified by using the stationary tower near the wind farm as a hard target.
These offsets were used to correct the observed azimuth and elevation angles from the scanning Lidars (as described in
Newsom and Krishnamurthy, 2020). Frequent hard target scans were conducted to evaluate any drift in the levelling of the
160 lidar, and none was observed during the period of study. The internal pitch and roll of the lidars were constantly below 0.1
degrees. In addition, boundary layer height estimates from a ceilometer at site A1 (also an inflow site) were used to evaluate
the impact of boundary layer structure on wind farm wake propagation. The wind turbines deployed at the King Plains wind
farm are GE 2.8 MW machines with a hub-height of 89 m and a rotor diameter (RD) of 127 m. The average lateral and

transverse distance in southerly wind directions between wind turbines (over the Eastern sector of the King Plains wind farm, intersecting sites A1 and H) is approximately 3.15 RD (S_x) and 14.57 RD (S_y). Site A2 is approximately 40 RD upwind of the first row of the King Plains wind farm, site A1 is approximately 2 RD upwind, and site H is approximately 22 RD downwind of the last row of the King Plains wind farm. Additional details on various instruments deployed at the AWAKEN site can be found in Moriarty et al., 2024.

Both scanning lidars installed at A2 and H run a composite scan routine that includes 20 minutes of six-beam profiling (Sathe et al., 2015) and 10 minutes of vertical stares. Wind profiles from 100 to 3000 m are obtained by applying the well-established least squares fit to the radial velocity measurement from the six-beams (Newsom and Krishnamurthy, 2020). Momentum flux is also estimated through the technique described in Appendix A.2 applied to the upstream and downstream beams based on the selected wind direction sector of interest (see Eq. A.3). In the following, momentum flux measurements from the surface sonic anemometer at the respective site are also combined with the lidar retrieval to extend the observable range down to the surface. Measurements only from southerly wind directions, specifically from 166 degrees to 190 degrees are considered in this analysis. Additionally, since removing all outliers from lidar observations is challenging, the median of the sample will be presented in the remainder of the manuscript.

Figure 2a shows the wind rose at 105 m above ground level from Doppler lidar measurements collected from March 17, 2023, to September 10, 2023. Wind directions are predominantly southerly during the duration of the study. Figure 2b shows the distribution of various atmospheric stability conditions as a function of wind direction. Atmospheric conditions were divided into various classes based on the Obukhov length (L) scale as provided in Krishnamurthy et al., 2021a and Table 1 below. Obukhov length, L , is given by

$$L = -\frac{u_*^3 T}{kg \langle w' \theta'_v \rangle}, \quad (3)$$

where T is the air temperature, g is the acceleration due to gravity, and $\langle w' \theta'_v \rangle$ is the kinematic heat flux from sonic anemometers.

At SGP C1 (which is ~21 km north of King Plains wind farm), stable atmospheric conditions are observed for more than 50% of the time. During neutral conditions, a larger percentage of winds are either easterly or northerly. It is important to note that surface atmospheric stability might not always be representative of conditions at elevated levels, especially during transition periods (i.e., during sunset and sunrise).

Table 1. Stability classification based on L thresholds.

Stratification	L
Very stable	$10 < L < 50$

Stable	$50 < L < 200$
Near-neutral stable	$200 < L < 500$
Neutral	$ L > 500$
Near-neutral unstable	$-500 < L < -200$
Unstable	$-200 < L < -100$
Very unstable	$-100 < L < -50$

3 Wake Recovery Observations

To minimize the impacts of wakes from neighboring wind farms (including the Breckinridge and Armadillo Flats wind farms shown in Figure 1) in our analysis and to measure the impact of wakes from at least 3 rows of wind turbines, measurements only from southerly wind directions, especially from 166 degrees to 190 degrees are considered. Since the wind directions are predominantly southerly, sufficient data is available (1490 10-min samples) to accurately estimate the mean trends of momentum flux during specific atmospheric conditions. Below, statistics of momentum flux variability under different atmospheric conditions, such as varying levels of thermal stratification (stability), the LLJs, high wind shear and veer conditions, ABL depth, and atmospheric gravity waves are assessed.

3.1 Impact of atmospheric stability on wake recovery

As shown in Figure 2b, when winds are southerly the atmospheric stability is predominantly (>50%) stable near the surface, with neutral conditions occurring about 20% of the time and unstable conditions observed for the remainder. Figure 3 shows median momentum flux ($\langle u'w' \rangle$) profiles from the downwind (site H) and upwind (site A2) locations during stable, neutral, and unstable atmospheric conditions. In general, we observe higher negative momentum flux upwind of the wind farm near the surface with an asymptotic behaviour eventually reaching zero near δ , like a canonical atmospheric boundary layer. Downwind of the wind farm, enhanced $-\langle u'w' \rangle$ is observed due to the shear and turbulence generated by the wind turbines. Stable conditions are observed to show larger deviations in momentum flux downwind of the wind farm compared to neutral or unstable atmospheric conditions. The sign of momentum flux is tied to the vertical wind shear, as for sustenance of turbulence within a wind farm an increase in wind shear (positive) should result in negative momentum flux downwind of the wind farm.

Therefore, in stable atmospheric conditions, due to large (positive) wind shear, the momentum flux must be negative to create downwind turbulence. As mentioned earlier, the wind farm wake propagates longer in stable conditions due to lower ambient turbulence compared to convective conditions, therefore at site A2 which is approximately 22 RD downwind of the last row of the King Plains wind farm, the region of enhanced vertical momentum flux due to the wind farm is expected to be more persistent and varies with the diurnal cycle (Figure 3a). In Figure 3b and Figure 3c, larger momentum flux estimates are observed near the surface during unstable and neutral atmospheric conditions compared to stable conditions. Under neutral conditions, where shear is less positive and ambient turbulence is higher compared to stable conditions, the momentum flux generated by downwind wind turbines is anticipated to be lower or less persistent. Consequently, wakes are not expected to travel as far. But in Figure 3b, significant momentum flux deficits are still observed at 22 RDs downwind during neutral conditions. A couple of possible reasons for this could be due to a) misclassification of atmospheric stability from surface flux measurements, i.e., surface atmospheric stability at hub-height is not representative of the true atmospheric state and b) higher wind shear observed during neutral conditions resulting in more negative momentum fluxes within the wind farm wake. The larger the vertical momentum flux, the faster the wake velocity recovers to a freestream value (Syed et al., 2023). While during

240 unstable atmospheric conditions, wakes are expected to dissipate faster (convective mixing of the atmospheric boundary layer) and due to low wind shear, the momentum flux deficits are expected to be significantly lower. In Figure 3c, it is evident that during unstable conditions the momentum flux deficits are lower but still observed 22 RD downwind. Overall, momentum flux deficits are greater during unstable conditions at higher altitudes, while they are larger during stable conditions at lower heights. One potential reason for deficits observed during unstable conditions at 22 RDs downwind could be the impact of
245 convective updrafts or downdrafts on the propagation of wake downwind of a wind farm (Berg et al., 2017, Wang et al., 2020). Additional analysis is required, ideally using high-resolution large-eddy simulations, to truly evaluate the impact of updrafts and downdrafts on wind farm wakes. Overall, the median deficit observed over King Plains wind farm shows that the flow disturbance downwind of a wind farm can extend long distances (at least 22 RDs) in every atmospheric condition. Such differences are generally not very evident from solely observing wind profile observations upwind and downwind of a
250 wind farm.

As mentioned earlier, no observations of vertical profiles of momentum flux have been recorded to date within an operational wind farm, therefore, there is limited knowledge on the height at which the peak transfer of momentum occurs downwind of a wind farm. It is well known that the peak velocity deficit (upwind – downwind velocity) generally occurs at hub-height, but there are no observations showing the peak momentum deficit above the wind farm. Based on large-eddy
255 simulation results, the peak momentum deficit is expected to occur near the upper edge of the wind turbine rotor layer (Abkar and Porte-Agel, 2015), but based on observations at King Plains wind farm, in stable conditions, at 22 RD downwind, peak momentum flux is consistently observed at ~ 0.36 RD above the wind farm. Therefore, the mean kinetic energy entrainment height into the wake is observed to occur higher than traditional LES models. Additional comparisons between LES models and observations are required to further evaluate the wake recovery processes within the wind farm wake.

260

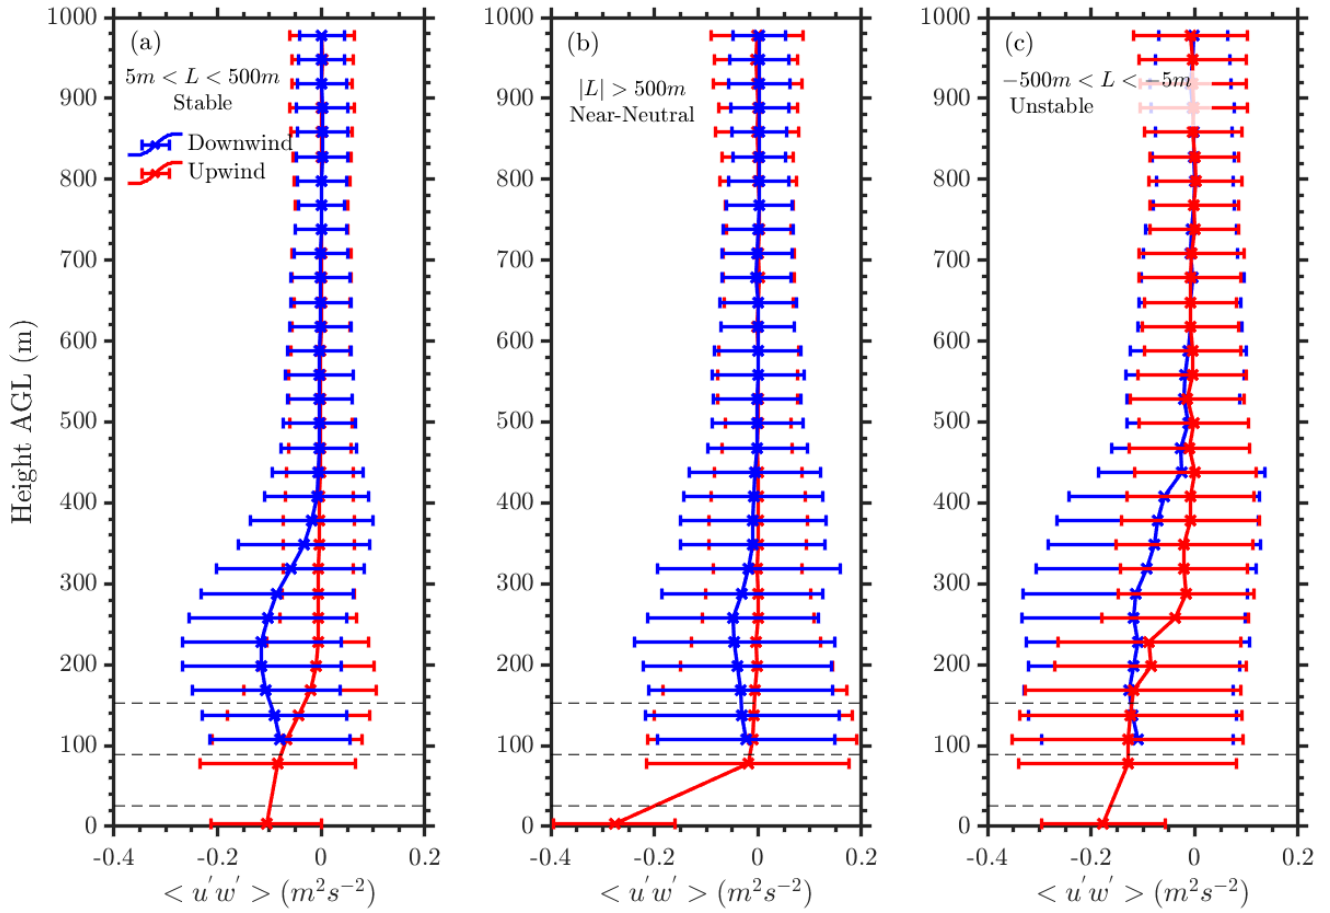

Figure 3. Momentum flux profiles at ~ 40 RD upwind (site A2) and 22 RD downwind (site H) of the King Plains wind farm during a) stable, b) near-neutral and c) unstable atmospheric conditions. The vertical extent of the wind turbine rotor layer is also shown with horizontal dotted black lines. Near surface Obukhov length (L) is used to differentiate between different stability conditions. Error bars represent the sample standard deviation at respective heights. Measurements only from southerly wind directions, specifically from 166 degrees to 190 degrees, and from 17 March 2023 to 10 September 2023 are considered in this analysis.

3.2 Impact of LLJs on wake recovery

Stable conditions produce LLJs in the U.S. Great Plains (Berg et al., 2015, Krishnamurthy et al., 2021a) whose characteristics can modulate wind farm performance/power output (Gadde and Stevens, 2020). There are several definitions of low-level jet height (Z_{LLJ}) in the literature (Blackadar, 1959, Bonner 1968, Whiteman et al., 1997, Song et al., 2005, Kalverla et al., 2019, Debnath et al., 2020) but in this article is defined as per Song et al., 2005. The definition is based on two criteria, 1) wind speed maximum (i.e., LLJ nose) is observed within the lowest 2-km and is greater than at least $>10 \text{ ms}^{-1}$, and 2) wind speed drop-off above the jet-nose is observed and above a set threshold (at a minimum $>5 \text{ ms}^{-1}$). Three categories of the LLJs were identified based on varying thresholds of drop-off speeds and maximum nose wind speed (Song et al., 2005), although in this analysis all LLJ categories were combined. Figure 4a shows the distribution of various near-surface atmospheric

stability classes during southerly wind directions (from 166 degrees to 190 degrees) during LLJ events and associated median Z_{LLJ} for each atmospheric stability class. It can be observed that lower Z_{LLJ} values are typically associated with very stable or stable near-surface atmospheric conditions, while higher Z_{LLJ} values are observed when the surface atmospheric stability is not stable, indicating a decoupled boundary layer (Vanderwende et al., 2015). Therefore, there could be confounding influences of the near surface stability and LLJ influence on the wind farm wakes during such instances. Figure 4b shows LLJ nose wind speed as a function of median Z_{LLJ} per wind speed bin and hub-height wind speed and Figure 4c shows Z_{LLJ} as a function of hub-height wind speed. It is evident that, up to near rated wind speed (approximately 13 ms^{-1}), a higher Z_{LLJ} results in a higher jet nose wind speed and a higher hub-height wind speed. Overall, it is challenging to decipher various processes influencing wind farm wake recovery using observations but would be possible to isolate certain common features known to influence wind farm recovery (such as LLJ height, or atmospheric stability or atmospheric boundary layer or hub-height wind speed) and study the variability observed during such select features.

As previously observed using historical measurements from the ARM SGP site, the Z_{LLJ} generally falls within 500 m above ground level (Debnath et al, 2023). Since the scanning lidar measurements start from ~ 100 m above ground level, in this analysis we only evaluate LLJs observed above the turbine hub-height (> 110 m). Therefore, the observations are partitioned into two halves, a) $250 \text{ m} < Z_{LLJ} < 500 \text{ m}$ and b) $110 \text{ m} < Z_{LLJ} < 250 \text{ m}$. The partitioning was driven by selecting a height near the wind turbine rotor layer (25.5 m to 152.5 m) that could be impacted by the wind turbine, considering the frequency of LLJ events from southerly wind directions (which peaked around 250 m above ground level), and the observed peak in momentum flux during stable conditions, which occurred approximately 250 m above ground level as shown in Figure 3. Figure 5 shows vertical profiles of momentum flux and wind speed both upwind and downwind of the wind farm for different Z_{LLJ} s as mentioned above and further conditioned to only southerly wind directions (166 degrees to 190 degrees). During southerly LLJ events at the King Plains wind farm, it is being observed that the transfer of momentum into the wake of the wind farm is a function of the LLJ height. Higher Z_{LLJ} is associated with larger momentum transfer within the wake and lower velocity deficit at 22 RD downwind. In short, the wake recovery is faster when the LLJ height is higher. This is mainly due to the shear generated turbulence below the Z_{LLJ} and the enhanced momentum deficit developed due to the wind farm. The peak entrainment height is observed to marginally increase with higher Z_{LLJ} . These results support some of the hypotheses from previous LES model results on this topic (Gadde and Stevens, 2020). One unique feature that is observed when $127 \text{ m} < Z_{LLJ} < 250 \text{ m}$, is that the Z_{LLJ} is modulated due to the presence of the wind farm downwind of the wind farm, wherein the Z_{LLJ} is consistently observed above the wind farm at 22 RD downwind. The downwind Z_{LLJ} is approximately equal to the height of the internal boundary layer (δ_{IBL}) generated due to the presence of the wind farm. In addition, during LLJ conditions, Z_{LLJ} is typically assumed to be the top of the atmospheric boundary layer (δ , Liu and Liang 2010), as the turbulence above the Z_{LLJ} is negligible. Figure 6 shows a schematic of the interaction between the wind farm, varying Z_{LLJ} s and growth of the internal boundary layer due to the presence of the wind farm. Figure 7 illustrates the probability distribution of LLJ events at the upwind site (A2) and downwind site (H) of the King Plains wind farm. The data reveal that the difference in LLJ height

between the upwind and downwind sites is greater below approximately 250 to 300 m but diminishes at higher LLJ heights. Notably, there is a reduced frequency of LLJs observed downwind of the wind farm when LLJs occur below the rotor layer. Future research will focus on further analyzing the effects of LLJs that occur beneath the turbine rotor layer.

315

Figure 4. (a) Distribution of various atmospheric stability classes (VS – Very Stable, Stable, NNS – Near-Neutral Stable, Neutral, NNUS – Near-Neutral Unstable, US – Unstable, VUS – Very Unstable, as per Sathe et al., 2015) during LLJ events from southerly wind directions and associated Z_{LLJ} per stability class, (b) median LLJ nose wind speed ($U_{LLJ,nose}$) as a function of Z_{LLJ} and hub-height wind speed (U_{hub}) at the upwind site (site A2), and (c) Z_{LLJ} as a function of U_{hub} . The error bars indicate one standard deviation. Minimum Z_{LLJ} is 110 m and maximum Z_{LLJ} is 690 m AGL. Measurements only from southerly wind directions, especially from 166 degrees to 190 degrees, and from 17 March 2023 to 10 September 2023 are considered in this analysis.

320

325 Figure 5. (a) Momentum flux and (b) horizontal wind speed profiles upwind (red, site A2) and downwind (blue, site H) of the King
 Plains wind farm during conditions when the Z_{LLJ} is less than 250 m AGL at the upwind location (dash-dotted) and Z_{LLJ} is between
 250 m and 500 m AGL (star dotted). The vertical extent of the wind turbine rotor layer is also shown with horizontal dotted black
 lines. Measurements only from southerly wind directions, especially from 166 degrees to 190 degrees, and from 17 March 2023 to
 10 September 2023 are considered in this analysis.

330

340 3.3 Impact during varying shear and veer (non-LLJ) conditions on wake recovery

High wind shear and veer conditions are generally observed within a wind farm, but it is difficult to decouple the effects of shear or veer conditions compared to atmospheric stability conditions. Nonetheless, it would be helpful to observe any consistent trends during such conditions as they are known to impact power production of a wind farm (Murphy et al., 2020). In addition, such findings may be informative for wind farm control concepts that yaw wind turbines away from the predominant wind direction at hub-height but do not currently consider the wind veer within the rotor layer (Fleming et al., 2019). Figure 8 and Figure 9 show median profiles of momentum flux and horizontal wind speed both upwind and downwind of the King Plains wind farm during non-LLJ events for various shear and veer conditions, respectively. Estimates associated with positive and negative wind shear or veer conditions during southerly wind directions are provided.

Hub-height wind speed ($U(H)$) and shear exponent (α) are estimated by fitting a power-law vertical wind profile to
350 the wind speed data available within the rotor layer (here from 90 m to 153 m, due to lack of observations below 90 m). The
power-law fit is conveniently recast into a linear fit through a log transformation as shown in Eq. 4 below:

$$\log U(z) = \log U(H) + \alpha \log \left(\frac{z}{H} \right) \quad (4)$$

365 Where $\log \log \left(\frac{z}{H} \right)$ and $\log \log U(z)$ are the independent and dependent variables of the linear fit, respectively. Hub-height
wind direction ($\phi(H)$) and veer ($\beta \equiv \frac{\partial \phi}{\partial z}$) are estimated in a similar fashion but using a linear wind veer model, as follows:

$$\phi(z) = \phi(H) + \beta(z - H) \quad (5)$$

360 This approach for estimating hub height quantities has the advantage of leveraging all the available measurements while
mitigating possible biases due to the lack of data in the lowest half of the rotor layer.

Certain trends are immediately observed for cases with positive or negative shear conditions (Figure 8), where
regardless of the wind shear profile, momentum deficits generated due to the wind farm are observed 22 RDs downwind of
the wind farm. But both wind and momentum deficits are higher during conditions with high wind shear ($0.5 < \alpha < 2$) compared
365 to low or negative wind shear ($\alpha \leq 0$) cases. Although a lower number of cases were recorded when the wind shear was low
or negative at the King Plains wind farm compared to high wind shear cases. Median wind speeds at hub-height during both
conditions are $\sim 5 \text{ ms}^{-1}$. For cases with negative wind shear, the median wind speed differences between upwind and downwind
are negligible but a clear trend in median momentum flux profiles are observed. Traditionally it is expected for the wind speed
to reach approximately 99% of the free stream wind speed, but in cases such as this where the wind speeds do reach near free
370 stream, it could be erroneously assumed that the wind farm wake has completely been dissipated (Djath and Schulz-
Stellenfleth, 2019). In reality, added turbulence due to the presence of a wind farm is not completely removed downwind of
a wind farm under such circumstances. Additional research is needed to evaluate wind farm wake models or parameterization
schemes during such canonical atmospheric conditions.

Although during cases with positive ($\beta > 0.1^\circ \text{ m}^{-1}$) and negative ($\beta < -0.1^\circ \text{ m}^{-1}$) wind veer conditions, median wind
375 speeds are closer to the cut-in wind speeds of the GE 2.8 MW wind turbines and therefore no momentum flux deficits are
observed (Figure 9). Both high and low wind veer cases show that the median wind speeds are relatively low at King Plains
wind farm. It is noted that the wind farm has also been observed to modify the wind direction downwind of a wind farm (not
shown).

Figure 8. (a) Momentum flux and (b) horizontal wind speed profiles upwind (red) and downwind (blue) of the King Plains wind farm during high ($0.5 < \alpha < 2$, observed 53% of time) and negative ($\alpha \leq 0$, observed 2% of the time) wind shear conditions. Measurements only from southerly wind directions, especially from 166 degrees to 190 degrees, and from 17 March 2023 to 10 September 2023 are considered in this analysis.

385

Figure 9. (a) Momentum flux and (b) horizontal wind speed profiles upwind (red) and downwind (blue) of the King Plains wind farm during high ($\beta > 0.1^\circ \text{m}^{-1}$, observed 28.5% of the time) and negative ($\beta < -0.1^\circ \text{m}^{-1}$, observed 1% of the time) wind veer conditions. Measurements only from southerly wind directions, especially from 166 degrees to 190 degrees, and from 17 March 2023 to 10 September 2023 are considered in this analysis.

390

3.4 Extent of wake within ABL

The atmospheric boundary-layer height (δ) is an important parameter for understanding the exchange of momentum, heat, and moisture between the free troposphere and the surface. Unfortunately, estimating δ can be challenging and there is limited consensus on the best approach to estimate δ from remote sensing instruments (Kottahaus et al., 2023). Typically, instruments such as scanning Doppler lidars or ceilometers are used to estimate δ (Tucker et al., 2009, Krishnamurthy et al., 2021b, Zhang et al., 2022). A ceilometer was deployed at the inflow site A1 and is used to estimate δ during southerly wind directions for this evaluation. The boundary layer (or mixing) height, provided by the Vaisala CL-31 BL-View software, is based on three different algorithms a) gradient method (where the algorithm detects the gradient in backscatter profile), b) profile method (where the algorithm determines the mixing height by fitting an idealized backscatter profile to the observed range-corrected ceilometer backscatter profiles) and c) merged gradient and profile fit method (Zhang et al., 2022). There are several filters applied to the data, such as cloud and precipitation filters, and additional outlier removal techniques (due to instrument noise). Figure 10 shows the median momentum flux and horizontal wind speed profiles during southerly wind directions and measurement co-located when concurrent ceilometer measurements were also available. The median δ (~540 m) at A1 from the ceilometer is below the height where both the median momentum flux estimates at sites A2 and H are near equal (~760 m). Therefore, it is observed that the median ceilometer δ does not accurately predict the height of the atmospheric boundary layer. There are several possible reasons for this, for example a) the ceilometer uses the gradient in backscatter aerosol concentrations to estimate δ , which might not always be the top of the boundary layer (Zhang et al., 2022), and b) upwind and downwind δ might be different due to the presence of the wind farm, therefore the δ estimated by the ceilometer well represents the δ at the inflow site (upwind momentum flux is observed to be close to zero). Above δ , the momentum flux deficits due to the presence of the wind farm are negligible. But overall, it is evident that the impact of the wind farms almost always reaches to the top of the atmospheric boundary layer. Therefore, it is important to model not only the wind turbine rotor layer with high vertical resolution but up to δ to accurately assess the impacts of wind farms and wake recovery.

415

Figure 10. (a) Momentum flux and (b) horizontal wind speed profiles upwind (red) and downwind (blue) of the King Plains wind farm for all atmospheric conditions. The median height of the ABL (δ) from ceilometer measurements is also shown. Measurements only from southerly wind directions, especially from 166 degrees to 190 degrees are considered in this analysis.

420

3.5 Impact of a gravity wave event on wake recovery

Figure 11 shows a time-height cross-section of vertical velocity as observed near ARM SGP central facility Doppler lidar (Newsom and Krishnamurthy, 2020, Krishnamurthy et al., 2021a) on 24th July 2023 from 0300 to 0400 hours UTC (1900 to 2000 hours local time). The vertical velocity clearly shows wave-like features at approximately 800 m AGL, where we

425 observe a positive and negative shift in vertical velocity. Figure 12 shows median momentum flux and wind speed both upwind
and downwind of the King Plains wind farm on 24th July 2023 from 0330 to 0400 UTC. The winds were predominantly
southerly during this event with a veer of 0.0375 °/m from surface up to the top of the boundary layer. A nocturnal LLJ
was also observed at approximately 220 m AGL at the inflow site and the gravity wave is propagating above the nocturnal stable
atmospheric boundary layer ($\sim Z_{LLJ}$). The peak-to-peak amplitude of the gravity wave is observed to be ~ 600 m, which spans
430 from 400 m above ~ 1000 m.

As observed in Figure 12, the momentum flux deficit is significantly enhanced above and within the wake of the King
Plains wind farm. Estimates of vertical momentum flux deficits are more than three times the median estimates of momentum
flux deficits observed during LLJ conditions (see Figure 5). Downwind, as previously noted, the peak of a LLJ is observed to
be displaced significantly above the wind farm which is a function of the enhanced mixing within the wind farm rotor layer.
435 The higher the mixing, the larger the entrainment, and the higher the displacement of the LLJ. Above the LLJ, the gravity
wave is observed to have an inverse effect, where the momentum flux is positive, entailing momentum is transferred upwards
to the gravity wave. The positive or negative transfer of momentum near the gravity wave probably depends on the updrafts
or downdrafts of the wave, but over the 30-min average observations the overall transfer of momentum is upwards. The
negative wind shear above the LLJ could also add to the extraction of momentum from the wind farm. This reduces the
440 intensity of the LLJ and the extracted momentum results in higher wind speeds above the LLJ downwind of the wind farm. It
is observed that, in this case, the wind farm has significantly altered the winds not only within the δ but also above it,
modulating the shape and intensity of the LLJ. Additional analysis would be needed to see the spatial impact of wind farms
during gravity wave propagation and power production. Next steps would be working towards a climatology of gravity waves
in the region and its impact on wind farm performance.

445 **Figure 11. Time-height cross-section of vertical velocity (W) at ARM SGP central facility on 24-Jul-2023 from 03:00 to 04:00 UTC. The gaps in data every 15-minutes are when the lidar performs wind profiles (Newsom and Krishnamurthy, 2020).**

450 **Figure 12.** (a) Momentum flux and (b) horizontal wind speed profiles upwind (red) and downwind (blue) of the King Plains wind farm during a gravity wave event on 24 July 2023 at 3:30 UTC.

4 Comparisons of observed δ_{IBL} with theoretical estimates

As discussed earlier, an internal boundary layer (δ_{IBL}) is developed due to a step change in surface roughness. Turbulence
 455 is expected to be higher within the internal boundary layer (downwind of the surface roughness) compared to inflow (upwind
 of the surface roughness). Wind farms create a step change in surface roughness and are known to develop internal boundary

layers downwind of a wind farm (Calaf et al., 2013, Stevens and Meneveau, 2017). In addition to the roughness impacts of the wind turbines, the wind farm developed internal boundary layer is convolved with the wake of the wind turbines, which create additional momentum deficits downwind of the wind farm. Internal boundary layers can be estimated from a velocity profile, by identifying a kink in the velocity profile (Garratt et al., 1990). Although this method provides a general trend, it is known to be not very accurate. An alternative technique, proposed in Stevens 2016, is being implemented here, where the difference in streamwise momentum flux profiles upwind and downwind of a surface roughness change are used to estimate the growth of the internal boundary layer. Vertical momentum flux is responsible for the influx of momentum into the wake of a wind farm. Larger streamwise momentum flux deficits above the wind farm are mainly observed due to turbulence and shear generated by the wind turbines. Wind turbine wakes enhance vertical mixing above a wind farm, which results in a downward flow of momentum. The internal boundary layer height (δ_{IBL}) is the height when the upwind and downwind momentum flux estimates are approximately within 1 – 5% of each other above the wind farm.

Wind farm δ_{IBL} is typically capped by δ but previously LES modelling results have shown to penetrate the upwind δ during LLJs (Gadde and Stevens, 2020). As shown earlier, model formulations exist to estimate δ_{IBL} downwind of a wind farm (Eq. 2). But the growth constant and wind farm surface roughness formulations have been fine-tuned based on large-eddy simulations, and as per the author's knowledge, no significant analysis on the validation of such formulations have been conducted so far using real-world observations. This article does not attempt to do that comparison in detail but is the start of such comparisons. The model formulations (Eq. 2) are sensitive to surface roughness in the presence of a wind farm ($z_{0, hi}$) estimates and the growth constant (C), which can significantly vary δ_{IBL} estimates within the model (sensitivity analysis not shown for brevity). The model formulations also do not explicitly restrict the growth of δ_{IBL} but are implicitly treated in models where the sub-grid scale mixing does not exceed δ , especially during stable atmospheric conditions.

Figure 13 shows the difference in estimates of δ_{IBL} from observations and model formulations (Eq. 2) only during stable atmospheric conditions and in the presence of a LLJ. Since we have higher confidence in δ_{IBL} during these cases and δ already represents the top of the LLJ height, this also avoids introducing additional uncertainty from Ceilometer δ observations. Some of the inputs to model formulations are provided by real-world observations, such as the lidar 10-minute average wind speed at hub-height, inflow surface friction velocity and roughness from sonic anemometers, thrust curve of the GE 2.8 MW wind turbine, and average wind turbine spacing in southerly wind directions. Given real-world inputs, the median δ_{IBL} difference between the model and observations is approximately 50 m, i.e., the model underestimates the δ_{IBL} . During some extreme cases ($\Delta\delta_{IBL} > 200$ m) the model does not behave due to in-consistent wind directions for a sustained period (several hours). Additional research is needed with large-eddy simulations or numerical weather prediction models with real-world forcing to assess the recovery and growth of δ_{IBL} at an operational wind farm.

490 **Figure 13. Probability distribution of δ_{IBL} difference between observations and a semi-empirical model (Eq. 2) during stable atmospheric conditions and in presence of a LLJ.**

5 Conclusions

These novel observations reveal the temporal and spatial variability of momentum balance within and above the wind farm wakes during regional specific atmospheric conditions. Profiles also show the growth of the internal boundary layer and allow quantification of the accuracy of current large-eddy simulation-based approximations in estimating the growth of the internal boundary layer (IBL).

500 The momentum balance surrounding a wind farm may impact wake recovery. The greater the momentum flux, the faster the wake velocity recovers to a freestream value. Wind farm wakes are known to propagate long distances during stable atmospheric conditions, and thereby the vertical momentum flux added due to the presence of the wind farm is more persistent at downwind locations and varies with the diurnal cycle. Stable conditions also produce LLJs in the US Great Plains, which are known to impact the performance and power output of commercial wind farms. Figure 6 shows a schematic of the impact of varying Z_{LLJ} on wind farm wake recovery and modulation of the flow downwind of the wind farm. Therefore, long-term measurements of vertical momentum flux upwind and downwind of a wind farm can provide a holistic view of the physical mechanisms behind wake recovery during various atmospheric conditions. In this study, we have evaluated the impact on wake recovery using long-term observations of vertical momentum flux through the boundary layer during a variety of atmospheric conditions. Overall, some highlights of the observations are mentioned below:

1. Wind farms alter LLJ characteristics downwind of the wind farm, by elevating the height of the jet above the wind farm (see Figure 5 and Figure 6),
- 510 2. The height of the LLJ significantly impacts wind farm wake recovery downwind, with higher Z_{LLJ} s resulting in faster wake recovery (see Figure 5 and Figure 6),
3. Negative wind shear during non-LLJ cases show short wake propagation at 22 RD downwind of a wind farm,
4. Wind farm wake impacts are observed through the δ (see Figure 10),
5. Gravity waves enhance wake recovery and accelerates winds above the LLJ downwind of a wind farm (see Figure 515 12), and lastly,
6. Large-eddy simulation-based theoretical δ_{IBL} models show a large spread given real-world inputs of the atmosphere and turbine.

Finally, we have highlighted several areas of research in this article that still need to be conducted to understand the dynamics of the wind farm influenced atmospheric boundary layer, mentioned below:

- 520 1. Additional comparisons between LES models and observations are required to further evaluate the wake recovery processes within a wind farm wake. Since most mesoscale wake model parameterizations are assessed using outputs from LES models.
2. It is important to model not only the wind turbine rotor layer with high vertical resolution but up to the top of the δ to accurately assess the impacts of wind farms and wake recovery (as shown in Figure 10). As it is important to 525 understand the entrainment of winds from the ABL to the wind farm wake boundary layer.
3. Recommend long term (1-year +) evaluation of wind farm wake models or parameterizations using long-term atmospheric flux observations through the boundary layer to assess the true performance of such models.
4. Analysis would be needed to see the spatial impact of wind farms during gravity wave propagation and power production.
- 530 5. Research is needed with large-eddy simulations or numerical weather prediction models with real-world forcing to assess the recovery and growth of δ_{IBL} at an operational wind farm.

Future work will focus on developing a methodology to classify gravity waves in the region and assess the power production impacts in the presence of gravity waves at the King Plains wind farm site. In addition, comparison of observations and models will be conducted to refine wind farm parameterization schemes within numerical weather models.

535

Appendix A: Flux estimation algorithms and approach

Herein we provide details of the algorithms used to estimate momentum fluxes from surface-based anemometers and scanning Doppler lidars and a methodology to estimate the height of the internal boundary layer from upwind and downwind momentum flux profiles.

540 A.1 Momentum flux estimates from sonic anemometers

Sonic anemometers are considered a standard for estimating atmospheric turbulence parameters (Wilczak et al., 2001, Wilczak et al., 2019, Fernando et al., 2019). Three-dimensional (3-D) acoustic anemometers provide measurements of winds and temperature at high temporal frequency (≥ 20 Hz), which supports calculation of higher order statistics with good accuracy (Cook and Sullivan, 2020). The sign conventions of the 3-D winds vary for different manufacturers and for Gill Sonic
545 anemometers, which were deployed for this project, the sign conventions are defined as positive for upward vertical wind component (w) and upward atmospheric fluxes, u wind component (North-South) is positive towards North and v wind component (East-West) is positive towards the West. The raw and flux data files are generated as per Cook and Sullivan, (2020), and contain 30-minutes of post-processed data and estimates of turbulent fluxes. The sonic data is post-processed by
550 first applying a de-spiking procedure (Goring and Nikora, 2002) to remove any data anomalies and a 2-axis coordinate rotation is performed (Wilczak et al., 2001), which ensures $\langle w \rangle = \langle v \rangle = 0$ and $\langle u_s \rangle = U$, where U is the mean wind speed, u_s is the streamwise component and $\langle \cdot \rangle$ is a 30-minute temporal average. To estimate the fluxes, the average of each variable is estimated over a 30-minute (non-overlapping) window and no detrending of the data is performed to estimate the velocity fluctuations. The stress tensor is then computed using 30-minute measurements of velocity fluctuations and assumed to be statistically stationary over the averaging window. Momentum flux estimates from sonic anemometer data were calculated
555 using the eddy-covariance method (Stull, 1988).

A.2 Momentum flux profiles from Doppler lidars

A brief description of the method to estimate momentum flux profiles from lidars is given below (Eberhard et al., 1989; Mann et al., 2010). The radial velocity (v_r) equation of a Doppler lidar is given by:

$$560 \quad v_r(R, \theta) = u(R) \sin \varphi \cos \theta + v(R) \sin \varphi \sin \theta + w(R) \cos \varphi, \quad (\text{A.1})$$

where, R is the range, φ is the half-opening angle of the conical scan (30°), θ is the azimuthal direction of the lidar beam (0 degrees is North), and (u, v, w) are the wind components at each range-gate center. The variance of v_r is given by

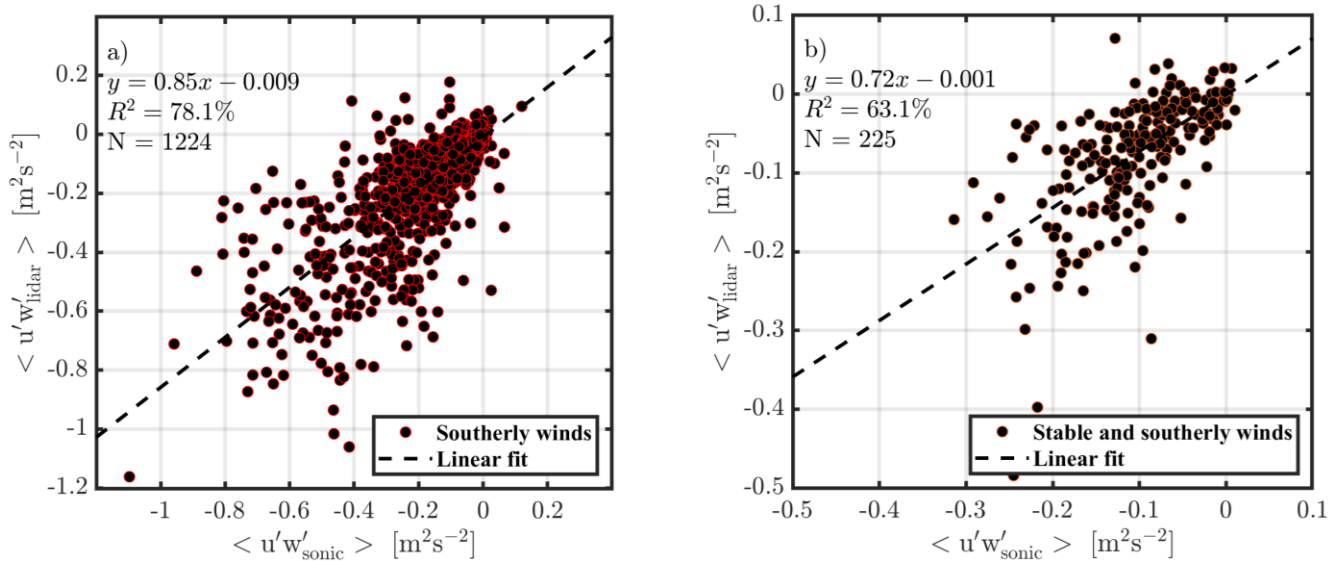

$$565 \quad \sigma^2[v_r(R, \theta)] = \sigma_u^2 \sin^2 \varphi \cos^2 \theta + \sigma_v^2 \sin^2 \varphi \sin^2 \theta + \sigma_w^2 \cos^2 \varphi + 2\langle u'v' \rangle \sin^2 \varphi \cos \theta \sin \theta + \\ 2\langle u'w' \rangle \cos \varphi \sin \varphi \cos \theta + 2\langle v'w' \rangle \cos \varphi \sin \varphi \sin \theta, \quad (\text{A.2})$$

where (u', v', w') are the velocity fluctuations. One can estimate the streamwise momentum flux components ($\langle u'w' \rangle$) by calculating the radial velocity variance in the upwind and downwind directions over 30-minutes (Eberhard et al., 1989; Mann
570 et al., 2010), which is then given by

$$\langle u'w' \rangle = \frac{\sigma^2[v_{r\ down}] - \sigma^2[v_{r\ up}]}{2 \sin 2\phi}, \quad (\text{A.3})$$

575 where, $\sigma^2[v_{r\ down}]$ and $\sigma^2[v_{r\ up}]$ are the radial velocity variances from the nearest downwind and upwind azimuth angles relative to the mean wind direction, respectively. The nearest up and down radial velocities from the azimuth angles are picked for each 30-minute sample and given range-gate wind direction estimate. It can be noted from Eq. A.3 that in a positively sheared turbulent flow, $\sigma^2(v_{r\ up}) > \sigma^2(v_{r\ down})$, i.e., the upwind variances, are typically larger than downwind variances. The effect of measurement volume is not considered in this analysis and has been shown to have a minimal impact on the streamwise momentum flux measurements for Doppler lidars (Mann et al., 2010).

580 For evaluating the accuracy of the algorithm, continuous Velocity Azimuth Display (VAD) scans at the same elevation and azimuth angles are required to calculate the variance of the radial velocity along each beam. From October 8, 2020, to January 14, 2021, continuous eight-point Planned Position Indicator (PPI) scans ($\Delta\text{az} = 45^\circ$ and $\text{el} = 60^\circ$) were conducted at the Atmospheric Radiation Measurement (ARM) Southern Great Plains (SGP) Central Facility to support an ongoing field campaign. The mean wind direction (ϕ) at each height is calculated using the approach of Newsom et al. (2017), wherein a
 585 chi-square distribution is fit to estimate the horizontal wind vector. Each beam was averaged for 6 seconds to provide a robust estimate of radial velocity and study the effect of noise from individual radial velocity measurements (Frehlich et al., 2001). This averaging could underestimate the variance observed by the lidar. During this study, each 360-degree wind profile was completed in ~1 minute. This provided the ability to calculate variance of radial velocity along each beam and the momentum flux profile using Eq. A.3. Along-wind momentum flux ($\langle u'w' \rangle$) estimates from the sonic anemometer at 60 m and lidar at 75
 590 m from southerly wind directions are shown in the Figure A1a.

595 **Figure A1: 30-minute averaged along-wind momentum flux ($\langle u'w' \rangle$) measurements from lidar at 75 m and sonic at 60 m AGL from October 8, 2020, to January 14, 2021, at ARM SGP central facility, for a) southerly wind directions under all atmospheric conditions and b) southerly wind directions under very stable atmospheric conditions ($10 \text{ m} < L < 150 \text{ m}$). A linear fit between the measurements ($y = mx + c$), coefficient of determination (R^2), and number of samples (N) are also shown. The X-axis scaling for (a) and (v) are different.**

Doppler lidar $\langle u'w' \rangle$ measurements are observed to correlate reasonably well to sonic anemometer $\langle u'w' \rangle$ measurements, with slope of 0.85 and a coefficient of determination of $\sim 78\%$. During stable atmospheric conditions, given the degree of stratification within the lidar probe volume, the lidar could be measuring very different atmospheric conditions compared to a sonic anemometer. Figure A1b shows measurements from southerly wind directions and very stable atmospheric conditions ($10 \text{ m} < L < 150 \text{ m}$). The coefficient of determination is observed to reduce during stable conditions to $\sim 63\%$, although the wind speeds are observed to correlate well under all conditions. The transfer of momentum is lowest in stable atmospheric conditions and therefore smaller momentum flux estimates are observed. From a purely statistical standpoint, the smaller magnitude of the fluxes also contributes to reducing the coefficient of determination, since under these conditions the contribution of instrumental and statistical noise to the physical variability of relatively larger. The scatter between lidar and sonic measurements are primarily due to (a) 15 m vertical and $\sim 250 \text{ m}$ horizontal separations between sonic anemometer and lidar measurements, (b) low temporal sampling of the lidar measurements, and (c) spatial averaging of the lidar pulse (range-gate = 30 m). These effects amplify during stable atmospheric conditions and result in larger scatter between measurements. Previous observations of momentum flux from profiling Doppler lidars have shown a similar accuracy when compared to sonic anemometers at various heights above ground level (Mann et al., 2010). Overall, the performance of the algorithm is expected to be adequate for the analysis being conducted in this article.
