## Abstract.

The complex dynamics introduced by floating platforms present new challenges in the study of wind turbine wakes, and numerous questions remain unresolved due to the early stage of this technology and limited operational experience. Previous studies showed that harmonic motions with realistic amplitude and frequency and under a modelled atmospheric boundary layer have no significant impact on time-averaged values, but that frequency signatures are still visible in spectra of wake parameters. The purpose of this work is to shed light on the spatio-temporal behaviour of the wake during imposed surge, heave and pitch harmonic motions. Wind tunnel experiments on the wake of a porous disc immersed in a modelled marine atmospheric boundary layer were performed and a phase-averaging method with kernel smoothing was applied to the data to extract the harmonic response of the wake. A quasi-steady-state analysis was carried out, showing that the phase-averaged observations appear to be larger than simple steady wake model predictions and revealing the dynamic nature of the wake responses to the motions. Thus, distinct wake dynamic hypotheses are formulated depending on the nature of the motion: (i) for heave, the wake is translated vertically while maintaining its integrity and containing the same power; (ii) for surge, the wake contracts and expands without any displacement of its centre localisation, accompanied with in-phase power modulation; (iii) and for pitch, the wake dynamics include both heave and surge impacts, with a vertical translation of the wake synchronised with crosswise wake surface and power modulations.

## 1 Introduction

In the context of a growing global energy demand, the Floating Offshore Wind Turbine (FOWT) technology shows a great potential. Unlike onshore, the offshore environment offers substantial advantages such as unobstructed wind flow and stronger winds, resulting in a higher capacity factor for installed wind turbines. The increasing distance from the coast provides access to stronger and more constant winds, which boost the wind turbine productivity from a capacity factor of 30-35% for new onshore installations to 42-55% for new offshore ones (Costanzo et al., 2023). Over the past decades, research on bottom-fixed wind turbines has led to a significant advance in the comprehension of their wake (Ainslie, 1988; Vermeer et al., 2003; Larsen et al., 2007; Porté-Agel et al., 2020). However, the intricate dynamics motion introduced by floating platforms poses new challenges with respect to wind turbine wakes and several questions remain unanswered due to the infancy of this technology

25 and the lack of feedback: the first pilot floating farm, made of 5 turbines, has been in operation since 2017 in Scotland (Hywind Scotland).

The floating motions depend on the platform technology itself (spar, tri-floater, barge, Tension Leg Platform, etc.) but the most widely studied motions are surge and pitch - *i.e.* fore-aft translation and rotation - as they represent the common case of aligned wind-waves (Porchetta et al., 2019). However, other motions such as sway and roll (side to side translation and  
30 rotation), and heave (up-down translation) are also studied in the literature. By defining the Strouhal number  $St = \frac{f \cdot D}{U_{\text{hub}}}$  and the normalised amplitude  $A^* = \frac{A}{D}$  where  $A$  and  $f$  are the motion amplitude and frequency, respectively,  $D$  the rotor diameter and  $U_{\text{hub}}$  the velocity at hub height, FOWT motions can be divided into two types: the high amplitude and low frequency ones ( $A^* \approx 0.1$ ,  $St < 0.3$ ) relative to mooring lines (Leimeister et al., 2018), and the low amplitude and high frequency ones ( $A^* \approx 0.01$ ,  $St > 0.5$ ) typically caused by a linear response of the platform to wave solicitation (Feist et al., 2021).

35 Several numerical and experimental studies investigated the effects of imposed or free motions on FOWT wake characteristics. Sebastian and Lackner (2013) showed that the different types of FOWT present significant unsteady aerodynamic loading for high Strouhal number motions ( $St > 0.5$ ). Bayati et al. (2017) evaluated the impact of high Strouhal number surge motions by wind tunnel experiments using hot-wire anemometry, and observed great unsteadiness and non-linearity in the wake. Bayati et al. (2018) and Fontanella et al. (2021) showed that surge motions impact the tip vortex, and by extension the near-wake,  
40 by adding energy to the wake. Other studies observed the impact of imposed motions in the near and far-wake with lower frequencies  $St \in [0.0085 : 0.28]$  in the case of low turbulence flows (Rockel et al., 2014; Fu et al., 2019; Kopperstad et al., 2020; Meng et al., 2022). They observed a faster wake recovery for imposed motion cases compared to the fixed one, due to a larger shear layer between the wake and the freestream, and an increased turbulent kinetic energy (TKE) in the wake.

Kopperstad et al. (2020) investigated the wake of a wind turbine mounted on a barge and a spar with wind tunnel experiments  
45 and CFD simulations, for uniform low and high turbulent inflow conditions with realistic mooring line motions ( $St < 0.25$ ). They showed that the higher pitch and surge platform motion amplitudes of the barge concept generate strong coherent flow structures, thus shear layer instabilities at the limit of the wake, resulting in a faster wake recovery. More recently, Li et al. (2022) studied the wake of a FOWT subjected to sway and roll motions using large-eddy simulations and linear stability analysis in uniform and low turbulent inflow conditions ( $TI < 4\%$ ). The results revealed that a turbine motion of  $St \in [0.2 : 0.6]$   
50 can trigger large-scale far-wake meandering even with low amplitudes ( $A^* = 0.01$ ). Messmer et al. (2024) studied in wind tunnel experiments a reduced-scale wind turbine under surge and sway motions in low turbulence intensity inflow conditions ( $TI \approx 0.3\%$ ). They showed that motion leads to a faster wake recovery for sway motions in a range of  $St \in [0.3 : 0.6]$ , and for surge motions in a range of  $St \in [0.3 : 0.9]$ . Like Li et al. (2022), they found that sway motions result in quasi-periodic meandering phenomena, while surge motions lead to streamwise pulsation in the wake for  $St \in [0.25 : 0.5]$  and lateral meandering  
55 for  $St \in [0.5 : 0.9]$ . Based on their numerical results, Kleine et al. (2022) concluded that motion impacts the tip vortices by exciting vortex instability modes almost identical to the motion itself. They noted that pitch motion shows a combination of heave and surge effects: vortices merge into one large structure coherent in the streamwise direction, as in surge, but vortices in the lower vertical direction coalesce faster than the ones in the higher vertical direction, approaching heave effects. Duan et al. (2022) observed that a wind turbine model under surge motion with  $St = 0.55$  formed periodical vortex rings in its wake,

not visible in surge motion with a higher Strouhal number. These effects were visible for all tested motion amplitudes, ranging from  $0.01D$  to  $0.06D$ .

In light of these studies and their results, three ranges of motion frequency can be defined according to their impact on the wake. The first one is motions at low Strouhal numbers ( $St < [0.1 : 0.2]$ ), where the wake is moved at a quasi-steady-state succession. At the opposite are motions at high Strouhal numbers ( $St > [0.6 : 0.7]$ ), where the motion impacts shear instabilities, at the wake borders. Between these two ranges are motions that enhance wake dynamics due to a higher receptivity of the wake to these perturbations.

The majority of previous studies were performed with low levels of turbulence and no shear inflow conditions. However, shear, higher turbulence intensity, and spectral contents developed by realistic atmospheric conditions may impact the wake differently and lead to other conclusions. FOWT wake studies under realistic inflow conditions are necessary to provide information on the impact of platform motions and to improve dynamic wake models in the context of floating wind farms. However, realistic atmospheric turbulent conditions lead to additional challenges. Turbulent structures contained in the approaching flow with a scale larger than the disc diameter are responsible for the appearance of wake meandering, a low-frequency non-harmonic phenomenon characterised by a global displacement of the wake (Larsen et al., 2007; España et al., 2011). Because of wake meandering, the wake location fluctuates in the crosswise direction. This generally results in a time-averaged wake that is larger than the instantaneous one, and wake radius or velocity deficit can be misjudged. To solve this issue, two reference frames are used to process the turbine wake statistics (Bingöl et al., 2009; Larsen et al., 2019; Jézéquel et al., 2022): (i) the Fixed Frame of Reference (FFoR), where the analysis is computed in the fixed reference of the experiments, and (ii) the Moving Frame of Reference (MFoR), where the wake statistics are analysed relative to the wake centre, preventing the spread of statistics caused by meandering.

The majority of experimental studies are performed with rotating wind turbine models, but the complexity of their design related to the difficulty of reproducing the right aerodynamic loads, especially under realistic turbulent conditions, caused by the absence of Reynolds similarity, leads to the use of porous disc models (España et al., 2011; Aubrun et al., 2013). Due to the absence of tip vortices and angular momentum, a porous disc can be considered as a far-wake generator, focusing the problem on the wake instabilities rather than on any other sources of instabilities. The concept of a porous disc is to reproduce the pressure difference found through the rotor of a real wind turbine. The turbulence and the rotational momentum created by each individual blade are not reproduced by this model, but it has been proven that these structures are negligible in the far-wake (Vermeer et al., 2003) - *i.e.* from  $3 - 4D$  downstream the wind turbine -, and that a three-blade rotating wind turbine and a porous disc present the same wake properties even under low turbulence intensity ( $I_u = 4\%$ , after a downstream distance of  $3D$  (Aubrun et al., 2013)).

Using the Atmospheric Boundary Layer (ABL) wind tunnel facility of the LHEEA (École Centrale de Nantes), Belvasi et al. (2022) and Schliffke et al. (2024) performed hot-wire and Stereo Particle Imagery Velocimetry (S-PIV) measurements with a porous disc subjected to low Strouhal number heave, surge and pitch motions ( $St \in [0.13 : 0.38]$ ) under realistic turbulent inflow conditions. In these wind tunnel experiments,  $4.6D$  and  $8.125D$  downstream of the FOWT model, they observed clear signatures of the harmonic motion frequencies in the spectra of the wake parameters, such as the wake centre or the available

95 power. These signatures are amplified with a higher Strouhal number motion, showing a fourfold energy spectrum amplitude increase from a surge motion of  $St = 0.25$  to  $St = 0.35$ . However they showed that, because of the high level of turbulence, the shear layer and the presence of meandering, due to the ABL modelling, the conventional time-averaged results are inappropriate to distinguish differences between cases with and without motions, and to observe the actual motion impact on the wake. The investigations revealed that, despite the frequency signatures, the imposed motions induce no discernible effect on velocity  
100 statistics, including streamwise velocity, its standard deviation or the turbulent kinetic energy. Additionally, the statistics of wake meandering, such as standard deviation, skewness and kurtosis of the wake centre coordinates, demonstrated no clear sensitivity to these imposed motions.

The aim of the present paper is to extend the previous work performed in realistic inflow conditions by studying the spatio-temporal wake behaviour and check whether the findings obtained at low turbulence intensity and uniform inflow still hold.  
105 In the present article, the position, surface, and available power of the far-wake of a porous disc are investigated by extracting the averaged phase, associated to the studied harmonic motions, from their time series. For this purpose, S-PIV experiments are conducted downwind of the porous disc subjected to heave, surge, and pitch harmonic motions and under a neutral marine ABL modelled at a reduced scale of 1 : 500. The unsteady wake properties are described in FFoR and in MFoR, given the presence of wake meandering, and a phase-averaged method with kernel smoothing is applied on the resulting velocity fields.  
110 Section 2 details the experimental methodology and the data post-processing, including the wake centre computation, essential for the MFoR, and the explanations of the phase-averaging method. The computational procedure and notations employed in this study are also presented in this section. Section 3 displays the phase-averaged results and Sect. 4 presents the analysis of the results in three parts, corresponding to the imposed motion. Finally, a conclusion is given in Sect. 5.

## 2 Methodology

### 115 2.1 Experimental set-up

#### 2.1.1 Atmospheric boundary layer physical modelling

Experiments were conducted in the atmospheric boundary layer wind tunnel of the LHEEA - Research Laboratory in Hydrodynamics, Energetics and Atmospheric Environment - at École Centrale de Nantes, in France. It is a  $2 \text{ m} \times 2 \text{ m}$  cross-section and 24 m long facility, with a 45 kW motor allowing a maximum flow velocity of 10 m/s. As described by Schliffke et al. (2024), a  
120 1:500 neutral marine ABL is modelled by a trip and spires installed at the entrance of the test section and by perforated metal plates placed on the ground, as shown in Fig. 1.

The resulting velocity profile corresponds to an ABL developing on a slightly rough terrain according to ?, with a roughness length  $z_0 = 5.7 \times 10^{-3} \text{ m}$  at full-scale, a power-law exponent  $\alpha = 0.11$  and a zero-plane displacement  $d_0 = 0 \text{ m}$ . The integral length-scale of turbulence is about  $^x L_u = 240 \text{ m}$  at hub height, while the target one is  $^x L_u = 250 \text{ m}$  according to Counihan  
125 (1975).

**Figure 1.** Experimental set-up in the atmospheric boundary layer wind tunnel at École Centrale de Nantes.

**Figure 2.** Normalised mean streamwise velocity profiles in the wind tunnel (a) and turbulence intensity profiles in the streamwise (b), transversal (c) and vertical (d) direction. The grey areas represent the turbine model height range and the black lines represent the range of turbulence intensity expected for a slightly rough terrain ESDU (1985). Figure from Schliffke et al. (2024).

Figure 2 shows the normalised longitudinal mean velocity  $U_{ABL}/U_{hub}$ , with  $U_{hub} = 2.9$  m/s the velocity at hub height, and the three components of the turbulence intensity measured in the wind tunnel, defined by the formula:  $I_i = \frac{\sigma_i}{U_{ABL}}$ ,  $i = u, v$  or  $w$ . More details on the turbulence and on the ABL modelling are presented in Schliffke et al. (2024).

### 2.1.2 Model description and test conditions

130 The model used in the wind tunnel is based on a 1:500 reduced-scale of a 2 MW floating wind turbine (80 m in diameter, 60 m in hub height, detailed by Choynet (2013)). In the test-section, this wind turbine is modelled by a porous disc with a diameter

of  $D = 160$  mm, a hub height of  $z_{\text{hub}} = 120$  mm and a surface of  $S_{\text{disc}} = \pi \frac{D^2}{4} = 0.020$  m<sup>2</sup> which gives a blockage ratio of 0.5% in the test section. It has a solidity of  $\sigma = 57\%$ , which is slightly below the limit at which vortex shedding can appear in the wake, a thrust coefficient of  $C_T = 0.65$  and a power coefficient of  $C_P = 0.25$  according to Aubrun et al. (2019). Figure 3 shows the 6 degrees of freedom of a FOWT and their definition.

**Figure 3.** Degrees of Freedom of a floating wind turbine platform. Surge ( $T_x$ ), and heave ( $T_z$ ) are the studied translation motions, and pitch ( $R_y$ ) is the studied rotation motion.

The motion amplitudes and frequencies of a barge-type platform were extracted from a data base of numerical simulations provided by BW-Ideol, and are specific to low-frequency motions related to the mooring lines acting on the floating platform. They were converted into values at reduced scale by using kinematic similarity, resulting in velocity scale and time scale factors between full and reduced scales of 2.5 and 200, respectively. More details are available in Schliffke et al. (2024). Porous disc motions are imposed by a 3-Degree-of-Freedom system, which allows floating wind turbine movements in the  $(x, z)$  plane. This study considers one heave case ( $T_z$ ), one surge case ( $T_x$ ) and two pitch cases ( $R_y$ ), in addition to one reference fixed case.

**Table 1.** Parameters of the motions imposed to the wind turbine model.

Motion	Full-scale amplitude	Full-scale period [s]	Model-scale amplitude	Model-scale frequency [Hz]	Normalised amplitude	Strouhal number
fixed	—	—	—	—	—	—
heave <b>H</b>	2.5 m	133	5 mm	1.5	0.03	0.09
surge <b>S</b>	5 m	100	10 mm	2	0.06	0.11
pitch <b>P<sub>0.14</sub></b>	4°	80	4°	2.5	4°	0.14
pitch <b>P<sub>0.28</sub></b>	4°	40	4°	5	4°	0.28

All motion cases, detailed in Table 1, are defined by a sinusoidal function along time  $t$ :

$$A_{motion}(t) = A \cdot \sin(2\pi f \cdot t) \quad (1)$$

Full scale configurations were downscaled to wind tunnel configurations by conserving the same normalised amplitudes and Strouhal numbers of the motions. The pitch motion has a rotation centre located at the floater level, and can be considered as a combination of tilt (pitch with a rotation axis at the disc centre), surge and heave motions: the  $4^\circ$  amplitude corresponds to a 8.4 mm amplitude surge with a 0.3 mm amplitude heave, as visible in Fig. 4.

**Figure 4.** Imposed motion amplitudes for heave (a), surge (b), and pitch (c). For heave and surge, the  $R_y$  curve is blended with the  $T_x$  and  $T_z$  ones, respectively.

### 2.1.3 Stereo-PIV system

An S-PIV system, represented in Fig. 1, is used to measure the three velocity components in the plan normal to the flow ( $y, z$ ), at  $x = 8.125D$  downstream of the turbine model. The flow is seeded by olive oil droplets with a diameter of  $1 \mu\text{m}$ , sprayed by a LaVision seeding system. The laser system is a Nd-YAG double cavity laser ( $2 \times 200 \text{ mJ}$ ), emitting 2 pulses with a wavelength of 532 nm at a time delay of  $350 \mu\text{s}$ , with an emission rate set to 14.1 Hz, avoiding phase-locking with the motions.

For each configuration, 14,000 image pairs are acquired by two sCMOS 5.5 Mpx HighSense Zyla cameras with 60 mm Nikon objective lenses, located on each side of the test section, as presented in Fig. 1. The mean field is subtracted to remove the persistent background and the resulting images are processed with a three-pass adaptive correlation from a  $128 \text{ px} \times 128 \text{ px}$  to a  $32 \text{ px} \times 32 \text{ px}$  interrogation window size with an overlap of 50%. Finally, the two-component vector fields are combined to reconstruct the instantaneous three-component velocity field.

## 2.2 Data processing

### 2.2.1 Wake centre tracking

160 In order to compute the statistics in the MFoR, the instantaneous wake centre is identified using the Weighted Geometric-Centre (WGC) method with an exponential weighting of the velocity deficit. WGC is a method already used in the literature with an exponential weighting by Muller et al. (2015) or without by Howland et al. (2016).

**Figure 5.** Presentation of the WGC algorithm steps: instantaneous velocity deficit field (black lines represent the threshold value contour) (a), Gaussian filtering (b), image binarization (c) and unification of the wake (d).

Figure 5 illustrates the algorithm: each instantaneous S-PIV vector field is computed as a velocity deficit field by removing the time-averaged freestream velocity field  $U_{ABL}$  (Fig. 5 (a)) and is smoothed by a Gaussian filter to reduce the influence of the local turbulence (Fig. 5 (b)). The Gaussian filter is defined as:

$$f_G(y, z) = \frac{1}{2\pi\sigma^2} \cdot \exp\left(-\frac{y^2 + z^2}{2\sigma^2}\right) \quad (2)$$

where  $\sigma = 3$  is the variance of the Gaussian function.

A binarization process is then performed, using a threshold velocity deficit set to  $U_{\text{thresh}} = 0.1U_{\text{hub}}$ , to determine the points that are part of the wake (Fig. 5 (c)). This process consists in pixel detection, inspired by watershed processing (Beucher, 2004), where each pixel verifies if its neighbouring pixels belong to the wake by comparing the local velocity deficit value to the threshold one. As in España et al. (2011), the wake is unified to decrease pixel noise (Fig. 5 (d)) and the final field provides the integration surface  $S_{\text{wk}}$  to be used in WGC to find the wake centre coordinates  $y_c$  and  $z_c$ :

$$\left( y_c(t) = \frac{\iint_{S_{\text{wk}}} y \cdot e^{\Delta u(t, y, z)} dy dz}{\iint_{S_{\text{wk}}} e^{\Delta u(t, y, z)} dy dz} \quad ; \quad z_c(t) = \frac{\iint_{S_{\text{wk}}} z \cdot e^{\Delta u(t, y, z)} dy dz}{\iint_{S_{\text{wk}}} e^{\Delta u(t, y, z)} dy dz} \right) \quad (3)$$

where  $\Delta u(t, y, z) = U_{ABL}(y, z) - u(t, y, z)$ , where  $u(t, y, z)$  is the instantaneous velocity and  $U_{ABL}(y, z)$  is the mean inflow velocity at point  $(y, z)$ .  $U_{ABL}$  is calculated for each case as the average of the velocity profiles of the mean field, at the S-PIV measurement plane limits, which present the lowest porous disc impact.

The results show that the lower part of the wake is truncated, as in Fig. 5, due to the S-PIV measurement plane definition. This truncation could potentially misrepresent the wake surface, but also the wake centre coordinates, especially for  $z_c$ . As

the wake descends, a new portion of the wake disappears under the S-PIV measurement plane, which leads to an "artificial" decrease in the wake surface and an increase in the wake centre  $z$ -coordinate. Tests with an ideal Gaussian wake showed a difference of  $0.1D$  between the WGC result and the real one when 20% of the wake is cut off, representative of the worst case here - *i.e.* when the porous disc is at the bottom. Thus, considering the up-down motions (mainly pitch motion cases), the amplitudes of the wake statistics in MFoR are misrepresented. The consequences for the analysis of the curve trends are limited, however.

In order to reduce this effect for the phase-averaged wake centres, a Gaussian fit approach is used. In this method, a least squared error method is computed between the S-PIV  $u$ -component velocity field and a 2D Gaussian function, defined by:

$$f_{\text{Gf}}(y, z) = A \cdot \exp \left[ -\frac{1}{2} \left( \frac{(y - y_c)^2}{\sigma_y^2} + \frac{(z - z_c)^2}{\sigma_z^2} \right) \right] \quad (4)$$

where  $A$  is the amplitude, and  $\sigma_y^2$  and  $\sigma_z^2$  are the variances of the Gaussian function in the  $y$  and  $z$  directions, respectively. The wake centre  $(y_c, z_c)$  found is the location of the centre of the 2D Gaussian function closest to the velocity field.

With the high level of turbulence, the instantaneous fields cannot be assimilated to a Gaussian distribution, and Gaussian fitting results in incoherent wake centre values. Thus, the WGC method is applied to the instantaneous velocity fields, and Gaussian fitting to the phase-averaged ones (the processes are detailed in Fig. 8).

### 2.2.2 Phase-averaging and kernel smoothing

The phase-averaging method is applied to the S-PIV velocity fields according to the harmonic motion imposed on the porous disc, in FFor and in MFoR. A kernel smoothing, defined by an Epanechnikov function (Wand and Jones, 1995; Hastie et al., 2009), is used to smooth the velocity deficit fields over phases. The Epanechnikov kernel smoother is defined as:

$$K_h(t_\phi, t) = \frac{3}{4h} \left( 1 - \left( \frac{t_\phi - t}{h \cdot \lambda} \right)^2 \right) \quad (5)$$

where  $t$  is the time,  $t_\phi$  is the reference time corresponding to the function maximum abscissa, and  $h$  and  $\lambda$  are the length scale and the bandwidth, also called window width, of the function, respectively.

Figure 6 illustrates the algorithm using the example of a noisy sinus function of period  $T$ : each sample  $m(t)$  (**a**) is associated to its respective reference time phase  $t_\phi$ , according to a phase  $\phi$  of the imposed harmonic motion (**b**), and the Epanechnikov kernel smoother  $K_h$  is computed for each phase increment to obtain the phase-averaged curve  $\tilde{m}$  (**c**):

$$\tilde{m}(t_\phi) = \frac{\sum_{i=1}^N K_h(t_\phi, t_i) \cdot m(t_i)}{\sum_{i=1}^N K_h(t_\phi, t_i)} \quad (6)$$

where  $N$  is the total number of data in the defined interval of the Epanechnikov function at the reference time  $t_\phi$  (corresponding to the gray zone in Fig. 6 (**c**)). The statistical uncertainties, using a confidence interval of 95%,  $I_{\tilde{m}}$ , are calculated using the

**Figure 6.** Phase averaging process example for a noisy sinus function  $m$  with a period of  $T$ : time series  $m(t)$  (a), phase association between data value  $m(t)$  and the phase of the harmonic signal  $\phi$  (b), and phase-averaging with kernel smoothing (function  $K_h(t_\phi, t_i)$ ) processing for each phase (c). The grey area in (c) represents the points used to compute  $\tilde{m}(t_\phi)$ .

formula:

$$I_{\tilde{m}}(t_\phi) = \left[ \tilde{m}(t_\phi) - 2 \frac{\sigma_{\tilde{m}}(t_\phi)}{N} ; \tilde{m}(t_\phi) + 2 \frac{\sigma_{\tilde{m}}(t_\phi)}{N} \right] \quad (7)$$

with  $\sigma_{\tilde{m}}$  the standard deviation of  $\tilde{m}$ :

$$\sigma_{\tilde{m}}(t_\phi) = \frac{\sum_{i=1}^N K_h(t_\phi, t_i) \cdot m(t_i)^2}{\sum_{i=1}^N K_h(t_\phi, t_i)} - \tilde{m}(t_\phi)^2 \quad (8)$$

210 Theoretically, the Epanechnikov function is a so-called 'optimal' kernel: the AMISE (Asymptotic Mean Integrated Square error) criterion of this kernel, which defines the global error of the function, is minimized whatever the sample size compared to other forms such as Gaussian or uniform (Wand and Jones, 1995). Nevertheless, the resulting values of kernel smoothing must be taken with caution, as the method acts like a low-pass filter and tends to limit extreme phenomena. Also, if a kernel function is too narrow, the result is based on too few data and paid too much attention to each particular piece of data, resulting

215 in an under-smoothed estimation. Conversely, if the kernel function is too large, the result takes too many data into account, resulting in an over-smoothed estimation. Thus, the choice of the bandwidth value  $\lambda$  is important. Here, after an iterative study to prevent either under or over-smoothed curves, the value was set equal to  $1/5$  the total number of phases.

### 2.3 Frames of reference and wake metrics

Because of wake meandering due to large turbulent structures in the inflow and of wake movements induced by imposed motions, the results are analysed from two perspectives: in the Fixed Frame of Reference (FFoR) and in the Moving Frame of Reference (MFOR).

**Figure 7.** Mean velocity deficit profiles  $U_{ABL} - U$ , normalised by the velocity at hub level  $U_{hub}$  for the fixed case in vertical (a) and lateral (b) direction centred on the wake centre coordinates  $(y_c, z_c)$  in FFoR (dashed lines), calculated with the Gaussian fit method, and in MFOR (full lines).

Figure 7 provides a comparison of the mean vertical and lateral velocity deficit profiles for the fixed case in both frames of reference. In the vertical direction (Fig. 7 (a)), the profiles show similar shapes, but the maxima of deficit are vertically shifted by  $-0.12D$  and  $-0.2D$  from the wake centre in FFoR and MFOR, respectively. This is partly due to the investigation area, which truncates the wake at the bottom, causing the WGC algorithm to artificially shift the wake centre higher in the vertical direction, as explained in Sect. 2.2.2. Another explanation is the presence of the ground, which asymmetrises the wake by distorting its lower part, and deviates the maximum of velocity deficit away from the actual wake centre. This is discernible with the profile in FFoR: it plunges toward the lower velocity deficit values faster at the bottom than at the top, showing a velocity difference of  $0.05U_{hub}$  reached with a height difference of  $0.33D$  and  $0.60D$  at the bottom and the top, respectively.

In the lateral direction (Fig. 7 (b)), either in FFoR or MFOR, the velocity deficit profiles exhibit the same shape with a maximum close to the wake centre. Velocity deficit profiles in FFoR are flatter than those in MFOR. The difference reaches  $0.04U_{hub}$  at the wake centre and are nearly null at the extrema of the wake. Moreover, the velocity deficit profile in MFOR is positioned slightly to the right of the wake centre, resulting in an intersection of the two profiles at  $y - y_c = -0.62D$  and  $y - y_c = 0.96D$ . Lastly, the selection of FFoR or MFOR significantly influences the velocity deficit profiles. Figure 7 illustrates

235 that, without a pre-processing wake centre tracking algorithm, there is a risk of underestimating the velocity deficit values, leading to an overestimation of the available power within the wake.

In this study, the wake parameters are computed according to the following procedure (illustrated in Fig. 8): (i) The mean inflow velocity field  $U_{ABL}$  is subtracted from each instantaneous velocity field  $u(t, y, z)$  to obtain the instantaneous velocity deficit field  $\Delta u(t, y, z)$ . (ii) The instantaneous wake centre coordinates  $(y_c(t), z_c(t))$  are computed, using the WGC method  
 240 described in Sect. 2.2.1, to obtain the velocity field in MFoR  $u_m(t, y - y_c(t), z - z_c(t))$  and the velocity deficit field in MFoR  $\Delta u_m(t, y - y_c(t), z - z_c(t))$  at each time step. (iii) Finally, the phase-averaging method with a kernel smoothing, as detailed in Sect. 2.2.2, is applied to the four fields, resulting in the phase-averaged velocity field  $\tilde{u}(\phi, y, z)$  and velocity deficit field  $\tilde{\Delta u}(\phi, y, z)$  in FFoR, and in the phase-averaged velocity field  $\tilde{u}_m(\phi, y - y_c(\phi), z - z_c(\phi))$  and velocity deficit field  $\tilde{\Delta u}_m(\phi, y - y_c(\phi), z - z_c(\phi))$  in MFoR.

245 From the fields in FFoR, are obtained for each phase  $\phi$ , the phase-averaged wake centre coordinates  $(\tilde{y}_c(\phi), \tilde{z}_c(\phi))$  calculated with the Gaussian fitting method described in Sect. 2.2.1, and the phase-averaged available power in FFoR defined as:

$$\tilde{P}(\phi) = \int_{S_{disc}} \frac{1}{2} \rho \tilde{u}(\phi, y, z)^3 ds \quad (9)$$

where  $\rho$  is the air density, integrated on a crosswise surface equal to the disc surface  $S_{disc}$ , representing the potential wind power a downstream turbine could produce. It is normalised by  $P_{ABL}$ , defined as the available power in the inflow, integrated  
 250 over the same surface:

$$P_{ABL} = \int_{S_{disc}} \frac{1}{2} \rho U_{ABL}(y, z)^3 ds \quad (10)$$

From the fields in MFoR, are obtained for each phase  $\phi$ , the phase-averaged wake surface  $\tilde{S}_{wk}(\phi)$ , defined by the integration surface used in the WGC method defined in Sect. 2.2.1, and the phase-averaged available power in MFoR defined as:

$$\tilde{P}_m(\phi) = \int_{S_{disc}} \frac{1}{2} \rho \tilde{u}_m(\phi, y - y_c(\phi), z - z_c(\phi))^3 ds \quad (11)$$

255 The integration is carried out on a crosswise surface equal to  $S_{disc}$ , and the result is normalised by  $P_{ABL}$ .  $\tilde{P}_m$  represents the actual power within the wake. With the WGC bias, considering the worst case - *i.e.* 20% of the wake truncated - the resulting  $\tilde{P}_m$  shows a relative error of about 14%. Thus, for the heave and pitch motion cases, the analysis will be essentially performed on the curve trends, and not on the amplitudes.

A summary of the wake parameters used in this work, and of the necessary computational methods, is presented in Fig.  
 260 8.  $(y_c(\phi), z_c(\phi))$  are the wake centre coordinates processed through the phase-averaged method applied to the velocity and velocity deficit fields in MFoR. They are not shown nor used in the present work.

### 3 Results

This section provides the phase-averaged results for the different motion cases. A global description is presented here; analyses are presented in Sect. 4.

**Figure 8.** Schematic view of the wake parameters used in this work and their connections. Boxed ones are velocity fields and bold ones are parameters analysed in this paper. (i) subtraction of the mean velocity field, (ii) calculation of the wake centre positions with the WGC method, and (iii) phase-averaging with kernel smoothing applied on the velocity fields.

Figure 9 presents the phase-averaged velocity deficit fields. Each column corresponds to a motion case and each row to a motion phase. The phases are  $[0; \frac{\pi}{3}; \frac{2\pi}{3}; \pi; \frac{4\pi}{3}; \frac{5\pi}{3}]$ , corresponding approximatively to the phases when the wake parameter extrema append. The dashed line circle represents the fixed porous disc emplacement. The full black line is the velocity deficit contour of  $U_{\text{thresh}}$  and the black cross is the wake centre calculated on the phase-averaged velocity field. The grey lines and crosses represent the time-averaged wake contour and wake centre, respectively.

In this figure, a preliminary analysis of the wake dynamics associated with the imposed motion can be conducted by comparing the black contours and crosses to the grey ones. In the fixed case (not shown here), the black contours and crosses coincide with the grey ones, indicating negligible velocity deficit modifications and the absence of periodic dynamics in this case. Therefore, any modifications in this figure, such as wake and wake centre movement or modifications in velocity deficit values, can be attributed to the imposed harmonic motion.

Regarding the heave case (**H** - first column), the first fields depict the wake with an axisymmetric shape, and the wake centre is located at the contour centre (**a**, **e**). Then, the wake is distorted with a wider contour at the bottom and the wake centre descends to its lowest point (**i**). Following this phase, both the wake centre and contour ascend, accompanied by an increase in its surface (**m**, **q**), until reaching their highest point (**u**). Moreover, the velocity deficit values are modified across the phases, following the ascend and descend of the wake with a maximum at phase  $\frac{5\pi}{3}$  (**u**) and a minimum at phase  $\frac{2\pi}{3}$  (**i**).

In the surge case (**S** - second column), the modifications are not as pronounced as for **H**. The wake centre does not move significantly and the wake contour maintains an axisymmetric shape throughout the phases. Nevertheless, there are notable modifications in the velocity deficit values, with a minimum amplitude at phase 0 (**b**) and a maximum at phase  $\pi$  (**n**), greater than those for **H**.

**Figure 9.** Phase-averaged velocity deficit fields  $\widetilde{\Delta u}$  normalised by the inlet velocity at hub height for different phases  $[0; \frac{\pi}{3}; \frac{2\pi}{3}; \pi; \frac{4\pi}{3}; \frac{5\pi}{3}]$  for **H**, **S**, **P<sub>0.14</sub>** and **P<sub>0.28</sub>**. The dashed line circle represents the porous disc emplacement, the black and grey full lines and crosses are the wake contours (0.1 normalised velocity deficit) and their centre, respectively (the black ones are the phase-averaged while the grey ones are the time-averaged ones). The associated phases are visible in the upper-left corner of the images in the first row.

Both pitch cases (**P<sub>0.14</sub>** and **P<sub>0.28</sub>** - last columns) exhibit similar wake dynamics to the heave case, involving an ascending and a descending movement of the overall wake. **P<sub>0.14</sub>** and **P<sub>0.28</sub>** have a  $\widetilde{z}_c$  minimum and a maximum wake contour deformations at phase  $\frac{\pi}{3}$  (**g**, **h**), an increase in  $\widetilde{z}_c$  and  $\widetilde{S}_{wk}$  (**k**, **l**, **o**, **p**) until a maximum at phase  $\frac{4\pi}{3}$  (**s**, **t**), followed by their reduction to close

the loop (**w**, **x**, **c**, **d**). Additionally, the pitch cases exhibit modifications in the velocity deficit values, similar to the surge case, with a minimum at phase  $\frac{\pi}{3}$  (**g**, **h**) and a maximum at phase  $\frac{4\pi}{3}$  (**s**, **t**). **P<sub>0.28</sub>** shows more pronounced modifications with higher wake centre and surface amplitudes, likely due to the higher wake receptivity, as observed by Schliffke et al. (2024).

**Figure 10.** Phase-averaged wake contours in MFOR for different phases  $[0; \frac{\pi}{3}; \frac{2\pi}{3}; \pi; \frac{4\pi}{3}; \frac{5\pi}{3}]$  for **H** (a), **S** (b), **P<sub>0.14</sub>** (c) and **P<sub>0.28</sub>** (d).

Figure 10 presents the contours of the wake, defined by the velocity deficit threshold value of  $U_{\text{thresh}}$  and calculated in MFOR for different phases, where each row corresponds to a motion case. The interest of this figure is that it enables the shape of the wake to be analysed by suppressing its displacement effect. The centre of each plot corresponds to the wake centre for all phases. The evolution of the wake contour of **H**, **P<sub>0.14</sub>** and **P<sub>0.28</sub>** consists of four distinct steps, as observed in the analysis of Fig. 9. Taking **P<sub>0.28</sub>** as an example (d), at phase 0 the wake has an axisymmetric shape. Then, the wake widens in the negative  $z$  area, resulting in a deformed shape, from phase  $\frac{\pi}{3}$  to  $\frac{5\pi}{3}$ . Its height increases until it reaches the maximum of the wake surface at phase  $\pi$ , before regaining its axisymmetric shape while decreasing its surface until phase 0, closing the loop.

These distinct steps are also visible for **H** and **P<sub>0.14</sub>**, with lesser modifications. Regarding **H**, it appears that the wake dynamics is shifted by an offset of  $\frac{\pi}{3}$ . The differences in the wake surface are notably pronounced at the bottom of the wake contour, where and when the wake is assumed to be flattened by the ground effects - *i.e.* from phase  $\frac{\pi}{3}$  to  $\pi$ .

Globally, as for FFOR velocity deficit fields (Fig. 9), the motion case **S** exhibits an axisymmetric shape throughout all phases in MFOR (b). The increase and decrease of the wake surface occur simultaneously in both  $y$  and  $z$  directions, but with a limited amplitude compared to the other motion cases. The surface reaches its minimum at phase 0 and its maximum at phase  $\pi$ .

Figure 11 shows the phase-averaged wake centre coordinates  $(\tilde{y}_c, \tilde{z}_c)$ , calculated with the WGC algorithm described in Sect. 2.2.1, and the mean fixed case values, depicted by the horizontal dashed lines. The coloured zones, representing the statistical uncertainties defined in Eq. 7, are not visible due to their small values.

Modifications of  $\tilde{y}_c$  are not significant, with peak-to-peak amplitudes ranging from  $0.02D$  for **P<sub>0.14</sub>** and  $0.08D$  for **P<sub>0.28</sub>**, whereas the peak-to-peak amplitudes of  $\tilde{z}_c$  are more pronounced with  $0.20D$ ,  $0.12D$ , and  $0.21D$  for **H**, **P<sub>0.14</sub>** and **P<sub>0.28</sub>**, respectively. The fact that all cases present slight modifications of  $\tilde{y}_c$  across the phases is certainly due to the motion directions investigated. Kleine et al. (2022) noted that motion impacts the wake with perturbations similar to the nature of the motion. Here, the porous disc movements (heave, surge, and pitch) do not present any  $y$ -direction component, resulting in low per-

turbations in the  $y$  direction. Moreover, **S** is the only motion with no movement in the  $z$  direction, resulting in minimal  $\tilde{z}_c$  modifications.

**Figure 11.** Phase-averaged wake centre  $y$ -coordinates  $\tilde{y}_c$  (a) and  $z$ -coordinates  $\tilde{z}_c$  (b) for the different motion cases, normalised by  $D$ . The coloured zones represent the statistical uncertainties of the phase-averaged values, defined in Eq. 7, and the horizontal dashed lines are the mean values for the fixed case. Each symbol corresponds to the phases shown in the previous S-PIV plane figures.

**Figure 12.** Phase-averaged wake surface  $\tilde{S}_{wk}$  normalised by  $S_{disc}$  (a), available power in FFoR  $\tilde{P}$  (b) and in MFoR  $\tilde{P}_m$  (c) normalised by the available power present in the ABL inflow  $P_{ABL}$ , for the different motion cases. Same as Fig. 11.

Figure 12 shows the phase-averaged wake surface  $\widetilde{S}_{wk}$ , the phase-averaged available power in FFoR  $\widetilde{P}$  and in MFoR  $\widetilde{P}_m$ , as defined in Sect. 2.3.  $\widetilde{S}_{wk}$  is computed in MFoR to avoid the overestimation present in FFoR on statistics in presence of wake movement.

All motion cases exhibit clear variations of wake surface, with peak-to-peak amplitudes ranging from  $0.48S_{disk}$  for **P<sub>0.28</sub>** to  $0.24S_{disk}$  for **S**. For cases **S**, **P<sub>0.14</sub>** and **P<sub>0.28</sub>**, these modifications are partially associated with changes in the velocity deficit values within the wake (Fig. 9). However, as mentioned earlier in Sect. 2.3, the truncated part of the wake may lead to an overestimation of the actual wake surface variations. Indeed, the cases showing the greatest  $\widetilde{S}_{wk}$  modifications are those with the highest  $\widetilde{z}_c$  ones - *i.e.* **H**, **P<sub>0.14</sub>**, and **P<sub>0.28</sub>**. These motion cases present  $\widetilde{S}_{wk}$  variations similar to the worst case presented in Sect. 2.3 (20% against 14%, 17%, and 21% for **H**, **P<sub>0.14</sub>**, and **P<sub>0.28</sub>**, respectively).

All cases exhibit clear  $\widetilde{P}$  variations, ranging from 8% for **H** to 13% for **P<sub>0.28</sub>**, compared to their mean value. These changes are inversely synchronised with  $\widetilde{z}_c$  for the **H**, **P<sub>0.14</sub>**, and **P<sub>0.28</sub>** cases - *i.e.* motions with a  $z$  direction movement. Thus, as for  $\widetilde{S}_{wk}$ , the  $\widetilde{P}$  modifications may be partially attributed to the S-PIV measurement area.

As said in Sect. 2.3, the analysis of  $\widetilde{P}_m$  was essentially performed on the curve trends and not on the amplitudes for the heave and pitch cases. For these cases,  $\widetilde{P}_m$  presents two different curve trends, with low variations of 3% and 4% for **H** and **P<sub>0.14</sub>**, respectively, compared to their mean value, and higher ones of 8% and 12% for **S** and **P<sub>0.28</sub>**, respectively.

## 4 Discussion

In this section, the results from the preceding section are analysed together, and the impacts of the motion on the porous disc wake are discussed for each type of movement successively: the study of the wake dynamics under heave motion (**H** - Sect. 4.1), surge motion (**S** - Sect. 4.2) and pitch motions (**P<sub>0.14</sub>** and **P<sub>0.28</sub>** - Sect. 4.3). Moreover, considering the low frequencies of the investigated motions ( $St < 0.3$ ), in this section, the results are compared to simple steady wake model predictions to evaluate whether the observed wake modifications are the result of successions of steady states rather than dynamic processes.

### 4.1 Heave motion

The present study of the heave motion effects suggests similarities with LES results from Li et al. (2022), manifesting a dynamic translation of the whole wake in the direction of the motion. Figure 13 shows a schematic view of the heave motion impact on the time evolution of the far-wake of a FOWT, with wake centre and wake surface modifications in the same order of magnitude as those found in the experiments. Heave motion causes the global wake to ascend and descend with the same period as the porous disc movement but with a higher amplitude, and slightly modifies the intrinsic parameters of the wake, such as the wake surface or available power.

Across all phases,  $\widetilde{y}_c$  shows minimal variations (Fig. 11 (a) and Fig. 12 (c)). This is expected since heave motion imposes a vertical movement on the porous disc. During heave motion, the porous disc moves in the shear layer, and is therefore subjected to a hub velocity modification. However, this modification is negligible (less than 2% (Fig. 2)), which is consistent with the low variations of  $\widetilde{P}_m$ .

**Figure 13.** Schematic view of the heave motion impact on the wake, based on the phase-averaged results. The FOWT is represented on the left and the phase evolution of its far-wake on the right.

345 The wake is moved vertically with more than three times the amplitude of the disc motion,  $0.1D$  for  $\tilde{z}_c$  amplitude variations, against  $A_H = 0.03D$ . In order to check whether this discrepancy could be due to a wake deflection effect, a quasi-steady-state analysis was conducted. The vertical displacement of the porous disc creates an inflow skew, which deflects the wake in the opposite direction to the movement. Thus, based on the velocity triangle between the streamwise hub velocity  $U_{hub}$  and the vertical maximum velocity induced by  $H$ , the maximum inflow skew angle to which the porous disc is subjected during the  
 350 heave motion is less than  $\pm 1^\circ$ .

Following the wake deflection model of Jiménez et al. (2010), a  $1^\circ$  inflow skew angle induces a vertical wake displacement of about  $0.05D$  at  $x = 8.125D$  (with  $C_T = 0.65$  and  $\beta = 0.09$ ), while the actual one is  $0.1D$ . The two values have the same order of magnitude, but previous studies demonstrated that the wake deflection model of Jiménez shows overestimation compared to wind tunnel measurements (Bastankhah and Porté-Agel, 2016; Porté-Agel et al., 2020), and that low yaw angles ( $< 10^\circ$ ) induce  
 355 negligible far-wake displacement (Bastankhah and Porté-Agel, 2015; Howland et al., 2016). Thus, heave motion impacts on the wake, at this amplitude and Strouhal number ( $A_H = 0.03D$ ,  $St_H = 0.09$ ), cannot be represented by a passive tracer approach: the perturbation created by the disc motion seems to be amplified in the wake.

## 4.2 Surge motion

Figure 14 presents a schematic view of the potential impact of surge motion on the far-wake of a FOWT, with wake surface and  
 360 available power modifications in the same order of magnitude as those found in the experiments. The hypothesis of the surge motion impact is that it does not move the wake in the  $(y, z)$  plane, but instead imposes a wake modulation, with an extension and a contraction of the wake surface in phase opposition with the available power variations.

**Figure 14.** Schematic view of the surge motion impact on the wake, based on the phase-averaged results. Same as Fig. 13.

The harmonic variations of  $\widetilde{S}_{wk}$  and  $\widetilde{P}_m$  illustrate a modulation of the wake surface and power according to the motion phase. These variations are synchronised, and the maximum  $\widetilde{S}_{wk}$  is reached at the same phase as the maximum  $\widetilde{P}_m$ , in agreement with

momentum conservation. This is similar to the pulsating wake dynamics observed by Messmer et al. (2024) on a rotating turbine model subjected to surge at higher Strouhal numbers ( $St \in [0.25 : 0.5]$  against  $St_S = 0.11$  here). Moreover, Duan et al. (2022) observed the formation of periodical vortex rings with surge with similar motion amplitudes but a higher Strouhal number ( $St = 0.55$ ). The authors also noted that these periodical vortex rings are not visible after  $6D$  and, that then, the wake swings left and right regularly. In the present study,  $8.125D$  downstream, this wake swinging is not visible but the surface variations could correspond to the passage of the periodical vortex rings on their residual signatures.

Across all phases,  $\widetilde{u}_m$  undergoes a variation of  $0.03U_{hub}$  at the wake centre (Fig. 11). As shown in Fig. 9, the porous disc motion induces a streamwise velocity variation of  $0.09U_{hub}$  maximum on the near wake. Therefore, following the wake model of Jensen (1983), this theoretically implies a velocity difference of  $0.01U_{hub}$ ,  $8.125D$  downstream of the porous disc (with  $C_T = 0.65$  and  $k_w = 0.045$ , the values for offshore turbines (Barthelmie et al., 2006, 2007; Cleve et al., 2008)), significantly lower than the total variation of velocity seen across the phases. This shows that, at this amplitude and Strouhal number ( $A_S = 0.01D$ ,  $St_S = 0.11$ ), surge motion impacts on the porous disc wake cannot be assimilated to a succession of steady states, and that the perturbation caused by the disc motion seems to be amplified in the wake.

### 4.3 Pitch motion

Figure 15 shows a schematic view of the potential impact of the pitch motion on the far-wake of a FOWT, with wake centre, wake surface, and available power modifications in the same order of magnitude as those found in the experiments. Pitch motions induce a vertical translation of the wake synchronised with wake surface and available power variations, leading to the hypothesis that its impact is a combination of the impacts of heave and surge, observed in the previous sections.

**Figure 15.** Schematic view of the pitch motion impact on the wake, based on the phase-averaged results. Same as Fig. 13.

In the present study, two pitch motion cases with different Strouhal numbers ( $St_{P_{0.14}} = 0.14$  and  $St_{P_{0.28}} = 0.28$ ) were analysed. They show approximatively the same trends, but with greater wake parameter variations for  $P_{0.28}$  compared to those of  $P_{0.14}$ , caused by a motion frequency closer to the natural frequency of the wake instabilities. Indeed, Li et al. (2022) showed that sway and roll motions with similar amplitudes and with a Strouhal number of about  $St = 0.2/0.3$  have the greatest impact on the far-wake, and Schliffke et al. (2024) showed that a porous disc subjected to surge motion with  $St = 0.35$  has a higher signature than a surge motion with  $St = 0.25$ ,  $4.6D$  downstream of the turbine model.

As seen in Fig. 4, the  $4^\circ$  pitch motions are a cinematic combination of  $4^\circ$  tilt,  $0.05D$  surge, and  $0.004D$  heave motions. A quasi-steady-state analysis was performed for each component of the pitch motion, divided into two categories: (i) the tilt and heave components, which induce an inflow skew, and (ii) the surge component, which induces wake velocity modifications.

The heave component amplitude is low, and induces a minimal inflow velocity modification in the ABL (Fig. 2). Thus, the velocity difference seen in pitch motion cases is not caused by the heave component, which is why the quasi-steady-state analysis on the wake velocity modifications was performed only on the surge component.

395 (i) Following the wake deflection model of Jiménez et al. (2010), the  $4^\circ$  tilt motion induces a vertical wake displacement of about  $0.08D$ . Even if the heave component has a low amplitude, its motion frequency, which is twice as high as the pitch motion, implies a non-negligible inflow skew. Indeed, the velocity triangles give inflow skews of  $0.5^\circ$  and  $1^\circ$ , resulting in a vertical wake deflection of  $0.01D$  and  $0.02D$  for  $\mathbf{P}_{0.14}$  and  $\mathbf{P}_{0.28}$ , respectively. Across the phases, the two component effects add up. With their different frequencies, the combined effects of the tilt and heave components could disturb the  $z_c$  curve (Fig.  
400 11 (b)), resulting in a distorted sinusoid shape.

According to the results (Fig. 11), the vertical wake displacement is about  $0.12D$  and  $0.21D$ , while the maximum wake deflection case - *i.e.* when tilt and heave are in phase - results theoretically in  $0.09D$  and  $0.1D$  for  $\mathbf{P}_{0.14}$  and  $\mathbf{P}_{0.28}$ , respectively. The values have the same order of magnitude, especially for  $\mathbf{P}_{0.14}$ , but as already mentioned for  $\mathbf{H}$ , the wake deflection model of Jiménez presents overestimations. Moreover, the  $\mathbf{P}_{0.28}$  case ( $A_{\mathbf{P}_{0.28}} = 4^\circ$ ) shows vertical translation variations similar to the  
405 ones obtained with a steady yaw angle of  $10^\circ$  (Bastankhah and Porté-Agel, 2015; Schottler et al., 2017), demonstrating this wake dynamic amplification. Thus, the perturbations created by the relative angles of the inflow, induced by the pitch motion cases, seem to be amplified in the wake, especially for  $\mathbf{P}_{0.28}$ .

(ii) Additionally to the vertical wake displacement, the pitch motions induce a velocity difference at the wake centre of  $0.03U_{\text{hub}}$  and  $0.05U_{\text{hub}}$  for  $\mathbf{P}_{0.14}$  and  $\mathbf{P}_{0.28}$ , respectively. According to the wake model of Jensen (1983), the  $0.05D$  amplitude  
410 surge theoretically implies a streamwise velocity difference of  $0.01U_{\text{hub}}$  and  $0.02U_{\text{hub}}$ , respectively,  $8.125D$  downstream of the porous disc (with  $C_T = 0.65$  and  $k_w = 0.045$ , as for  $\mathbf{S}$ ). As for the surge motion case, the theoretical values are lower than the experimental ones, showing that the perturbation relative to the surge component seems to be amplified in the wake.

Further investigations are required to confirm if the porous disc under tilt only motion exhibits these wake parameter modulations, as it will not generate any additional surge component of motion. Moreover, the heave component effect on the wake  
415 needs to be studied ; as its frequency is higher, it can affect the wake even if its amplitude is relatively low.

## 5 Conclusions

The present work proposed a description of the dynamic response of a wind turbine wake observed in previous studies when a turbine model is subjected to harmonic motions (Belvasi et al., 2022; Schliffke et al., 2024). All experiments were performed in the Atmospheric Boundary Layer wind tunnel of the LHEEA at École Centrale de Nantes, where a 1:500 neutral marine  
420 ABL was modelled. Three different platform movements are analysed: heave, surge and pitch motions.

These cases are harmonic, with realistic amplitudes and frequencies according to a full-scale 2 MW wind turbine combined with a barge-type floater. The chosen amplitudes/frequencies are relative to the second-order motions due to the response of the floater linked to mooring lines and anchoring characteristics. A Stereo-PIV system was used, measuring the three-component velocity field in a plane normal to the freestream flow  $8.125D$  downstream of the model. Phase-averaging with

425 kernel smoothing was applied on the velocity fields represented in the fixed and the moving frames of reference in order to study the motion impacts on the wake and their effects on a potential downwind turbine. The results suggest that the floater movements add coherent spatio-temporal behaviours to the wake of a FOWT, by modulating the cross-wise wake positions, the wake surface, and the available power, with amplitudes higher than those expected by using basic quasi-steady-state approaches. Thus, several hypotheses and conclusions have been drawn:

- 430 – The moving frame of reference calculation method and the phase-averaging with kernel smoothing algorithm, used in this study, enable the observation of coherent spatio-temporal wake behaviour of a turbine model under realistic conditions of turbulence. Thus, the first method avoids the wake parameter misestimations caused by the presence of wake meandering due to the large turbulent structures present in the inflow, and the second separates the periodic velocity fluctuations due to motion and the background turbulence.
- 435 – Heave motion translates the wake vertically with an amplitude higher than the motion itself. The inconsistent evolution of the wake surface and the available power variations might be partly associated to a processing bias and to a ground effect.
- Surge motion leads to contraction and expansion of the wake surface in the crosswise plane, with negligible wake displacement, and modifies the available power within the wake. The results show that wake crosswise surface and velocity modulations are in phase opposition: a large wake surface implies a low power in the wake, and vice versa,
- 440 consistent with momentum conservation.
- Pitch motion involves a combination of heave and surge motions. As for the heave motion, the wake is translated vertically, and, as for the surge motion, the wake surface and available power values are modulated in phase. The results show that the two wake dynamics are synchronised: when the wake goes to its highest point, it has a large surface and
- 445 a low available power. However, this synchronisation is phase-shifted by  $\frac{\pi}{3}$ , partly caused by the processing bias and by a ground effect as for the heave motion case, or caused by the heave component, intrinsic to pitch motion that has twice its frequency.

Despite the use of a porous disc that prevents the near-wake flow from the presence of tip vortices and rotational momentum, the wake dynamics is modified by the disc motions. It is assumed that the present wake dynamics are directly the result of

450 flow perturbations initiated by the porous disc motions in the near-wake and amplified in the far-wake. This diverges from previous interpretations arguing that the flow perturbations related to floating movements are due to the tip vortices impacted by the turbine motion and interacting with each others (Kleine et al., 2022). A comparison between a porous disc and a rotating model, with realistic power and thrust curves, both immersed in an atmospheric boundary layer and subjected to floating motions, are needed to discriminate the effective influence of the tip vortices and/or rotational momentum on wake dynamics.

455 *Data availability.* The raw data of each final figure will be available on an open research repository.

*Author contributions.* BC designed and performed the experiments. AH coded the post-processing methodology, processed and analysed the data under the supervision of and in discussion with BC and SA. SA was responsible for funding acquisition and project administration. The original draft was written by AH and reviewed and edited by SA and BC.

*Competing interests.* One of the co-authors is a member of the editorial board of the journal Wind Energy Science.

460 *Acknowledgements.* This work was carried out within the framework of the WEAMEC, West Atlantic Marine Energy Community, and with funding from the Pays de la Loire Region and the École Centrale de Nantes. The authors wish to acknowledge Titouan Olivier-Martin for helping with the installation of the wind tunnel experimental set-up. Additionally, large credit to Thibaud Piquet for his impressive support in getting the S-PIV system operational despite the many twists and turns.
