**Abstract.** Large offshore wind farms face operational challenges due to turbine wakes, which can reduce energy yield and increase structural fatigue. These problems may be mitigated through wind farm flow control techniques, which require reliable wake detection (recognising the presence of a clear wake) and characterisation (parametric description of a wake's properties) as prerequisites. This paper presents a novel three-stage framework for generalised wake detection and characterisation. First, a regression model utilises blade loads and SCADA data to estimate the wind speed distribution across the rotor plane. Second, a convolutional neural network undertakes pattern recognition analysis to perform the wake detection, classifying rotor-plane wind estimates as 'fully-impinged', 'left-impinged', 'right-impinged' or 'not impinged.' Third, where wake impingement is detected, two-dimensional Gaussian fitting is undertaken to provide a parametric wake characterisation, providing outputs of the wake centre location and wake lateral width. The framework is tested in a simulation environment incorporating the Mann turbulence model, DWM model for generating wakes and BHawC aeroelastic code. The testing is undertaken under a wide range of wind conditions, with mean ambient wind speeds from 5-15 m/s, turbulence intensities from 3-9% and full range of wind directions. Results show high accuracy of wind field estimation, with the mean RMSE over all test cases being 3.7% when normalised by mean ambient wind speed. A wake detection sensitivity study confirms accurate performance across a majority of wind conditions, with minor issues observed only for more extreme conditions or those at the limits of the utilised training data. The final wake characterisation stage is shown to flexibly adapt to changing wind conditions, successfully tracking the wake's position even for more turbulent conditions. The proposed framework therefore demonstrates strong potential as a generalised approach to wake detection and characterisation.

## 1 Introduction

The wind industry has advanced significantly in recent years, reaching a total worldwide installed capacity of 906 GW at the end of 2022 (Hutchinson and Zhao, 2023). Despite being a mature field, some challenges still remain to be solved. Due to the increasing size of modern wind farms, there is a newly-posed challenge of effectively operating clusters of hundreds of multi-megawatt machines. For this reason, the current focus for both research and industry is shifting towards a farm-level approach for operations, control and maintenance.

A wind turbine interacts with the incoming wind flow, extracting energy and creating a wake: a downstream region of decreased wind speed and increased turbulence. Due to their varied impact on the farm's performance, the wakes play a crucial role in turbine operation. A turbine affected by wakes from upstream machines has a lower energy yield due to a wake-generated velocity deficit in the upcoming flow (Adaramola and Krogstad, 2011; Barthelmie et al., 2010). Having the rotor experience a more turbulent wind field also leads to uneven aerodynamic loading on the machine, inducing severe fatigue cycles in its structure (Churchfield et al., 2012). A turbine under waked flow conditions is also prone to experiencing additional turbulence due to large-scale motions of wake meandering, creating substantial loads and thus fatigue (Madsen et al., 2010; Larsen et al., 2013).

Via various control techniques it is possible to mitigate the negatives of waked flow conditions, optimizing turbine operation for reliable and effective performance. Probably the earliest developments in this area date back to a study by Steinbuch et al. (1988), where the authors implement axial induction control to increase the energy yield by reducing the wake effects. Numerous methods for optimizing the wind farm flow follow; some examples include wake steering by introducing yaw offsets (Howland et al., 2020; SGRE, 2019), or dynamic individual pitch control (Frederik et al., 2020) and dynamic induction control (Munters and Meyers, 2018) to induce enhanced mixing in the wake.

To use the above-mentioned approaches in a closed-loop control scheme, dynamic information on whether the impinging wake is being successfully redirected or dispersed is required (Raach et al., 2016). Moreover, before starting the control action, there first needs to be a confirmation that a turbine is indeed wake-affected to facilitate an intervention to its normal operating cycle. For the sake of the discussion in this work, we term these two flow control prerequisites *wake detection* and *wake characterisation*. By the former we refer to the action of recognising that a given turbine is experiencing a clear wake impingement from a nearby machine, in such a way that it has a significant (in both magnitude and time) influence on its performance. By the latter we refer to the action of identifying the properties of the wake using a simplified parametric representation, and monitoring how the values of these parameters change in time.

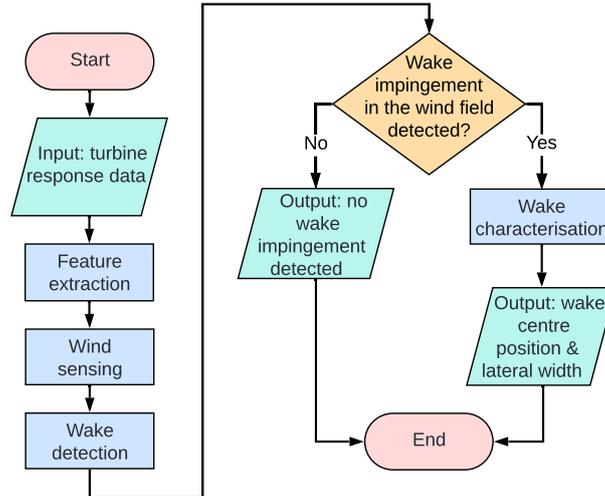

There is a growing effort in the research community to develop new wake detection and characterisation techniques. Up-to-date approaches focus on implementing remote sensing techniques or using a turbine's operational data. The former is usually achieved with the use of Light Detection and Ranging (LIDAR) devices, with recent literature featuring numerous examples of their successful application in wake characterisation (Bingöl et al., 2010; Trujillo et al., 2011; Conti et al., 2020; Lio et al., 2020). A recent study (Raach et al., 2016) investigates the use of LIDAR-based wake characterisation directly in a closed-loop wake steering scheme, showing promising results. Despite achieving great performance, the LIDAR-based approaches unavoidably rely on an additional hardware, which is not currently present at most wind farms and represents a significant additional cost. A different way of tackling the problem is to employ the relationship between wind field and turbine response. The basic idea behind this approach is that a variation in the incoming flow can be correlated with changes in signals such as blade root bending moments and generator speed. The widely discussed method introduced by Bottasso and Schreiber (2018) relies on using the out-of-plane blade root bending moments to approximate the local wind speed in each of the rotor quadrants, thus allowing for partial wake detection. The method is tested in the field (Schreiber et al., 2020) using a setup of two wind turbines and a met mast, providing a proof of concept for the qualitative wake detection. The idea of mapping between the

blade loads and local wind speeds is also used by others, some examples include studies by Kim et al. (2023), Simley and Pao (2016) and Liu et al. (2021). A study by Onnen et al. (2022) pushes this approach further, implementing both in-plane and out-of-plane blade loads to achieve accurate characterisation of the meandering wake deficit with the use of Extended Kalman Filter (EKF). The authors also discuss the potential of using the estimation uncertainty metric to detect the wake presence. The method is validated via wind tunnel (Onnen et al., 2023) and field (Onnen et al., 2025) experiments, showing a strong correlation between the estimated wake position and the reference LIDAR measurements. A similar blade-load-based approach is also considered by Dong et al. (2021), where the authors investigate wake characterisation with an EKF setup within a simulation environment. In another study by Farrell et al. (2022), the authors implement a recurrent neural network trained with experimental and simulation data to estimate the lateral position of the wake centre.

All in all, we identify the research gap as follows: the existing wake estimation methods primarily focus on the wake characterisation aspect, with both LIDAR- and load-based approaches offering high accuracy. The up-to-date wake detection studies analysed the wake impingement in a scenario with a single upwind turbine, for a fixed set of wind directions. This handles only a part of the overall problem in a realistic setting, where the turbine experiences a full range of wind directions. For the majority of inflow angles the turbine is not directly affected by a nearby turbine's wake, it does however receive a large amount of random flow fluctuations due to operating in the highly turbulent atmospheric boundary layer. Without a robust knowledge of whether the turbine operates under wake impingement or not, there is a risk of implementing a wake characterisation scheme on a naturally occurring turbulent eddy, hence providing incorrect and misleading inputs to the control system.

In this paper, we seek to bridge the above identified gap by proposing a generalised 3-stage approach that performs wind field reconstruction, wake detection and wake characterisation within a single framework. Firstly, the instantaneous wind field interacting with the rotor is estimated using turbine operational and load data. Secondly, a neural network approach is implemented for classifying whether the estimated wind field represents a case of 'full', 'partial' or 'no' wake impingement. Thirdly, if clear wake impingement is detected, a parametric wake model is fitted in order to characterise the centre and lateral-width of the currently observed wake. A novel end-to-end methodology is presented, which aims to provide both a demonstrator and a performance benchmark for generalised wake detection and characterisation methods of this type. The models are trained and tested for a full range of wind directions within a virtual offshore wind farm. The simulation environment incorporates Mann turbulence wind boxes, Dynamic Wake Meandering (DWM) model for generating wake interactions, and aeroelastic code to compute the turbine response. This work focuses on developing a novel solution that can confidently assert when a turbine is impinged by a wake from a nearby machine - this being a key factor for farm-wide wake steering control.

The paper is structured as follows: Sect. 2 discusses the methodology used for the framework's development and training; Sect. 3 presents the results of the framework validation; Sect. 4 considers the discussion on the framework applicability and limitations; and lastly, Sect. 5 covers the conclusion and addresses future work.

**Figure 1.** A flowchart describing the proposed wake estimation framework.

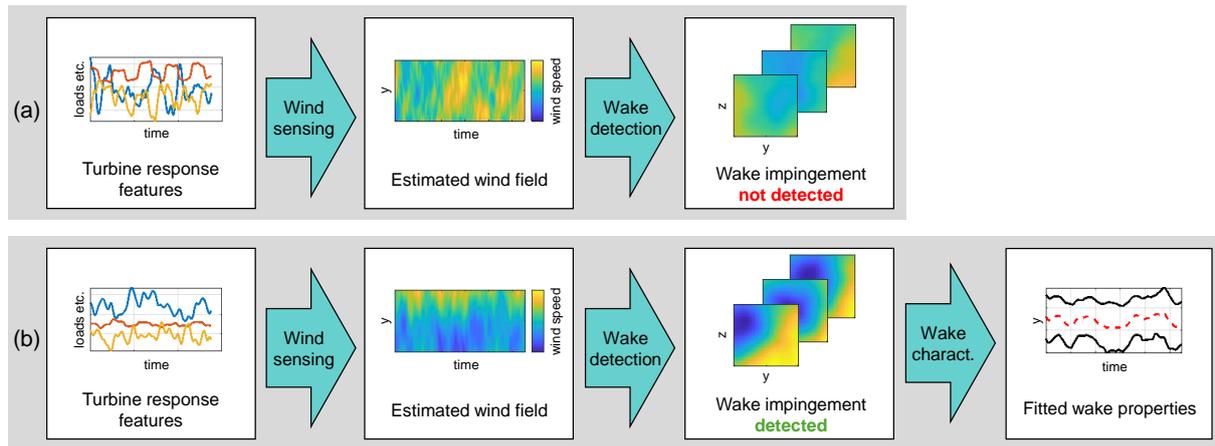

## 2 Methodology

Section 2.1 discusses the layout of the developed framework and its high-level characteristics. The details of the implementation are described in Sect. 2.2 to 2.5.

### 2.1 A summary of the proposed framework

95 Figure 1 shows the information flow between the models within the proposed wake estimation framework. Figure 2 presents two examples that illustrate the framework’s performance when (a) the wind field doesn’t have a clear wake impingement from a nearby turbine, (b) when it does. The high-level details of the individual models that the framework consists of are discussed below.

The first constituent model in the developed framework is a wind field estimator, which when provided with turbine response  
 100 time series as the input, is capable of producing the wind field representation, thus showing the flow at the rotor as the output. This process is hereafter referred to as *wind sensing*. A successfully generated wind field estimation provides sufficient information to analyze the flow field and extract the desired wake impingement information. For this framework, we propose to perform wake detection using a Convolutional Neural Network (CNN), which, after being trained, can distinguish the flow with a well-defined wake deficit from a nearby turbine. If a likely wake impingement is detected, a suitable algorithm aiming  
 105 to estimate the wake’s properties is to be implemented. The ultimate framework output data are two time series of the wake centre position and wake lateral width, describing the horizontal distance where the degree of wake impingement is significant. The combination of these two time series provides a simplified two-dimensional representation of a meandering wake deficit. This representation can serve as an input to wind farm flow control techniques that are informed by the lateral properties of the

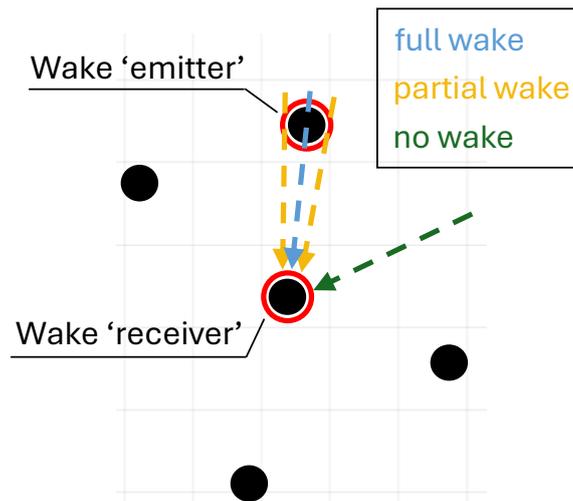

**Figure 2.** Two examples showing the framework’s performance: (a) the incoming wind field doesn’t have a clear wake deficit, thus the framework doesn’t go into the wake characterisation; (b) there is a clear wake deficit, thus the final step of wake characterisation is implemented.

impinging wake, such as those that use yaw as a control action (Howland et al., 2020; SGRE, 2019). Focusing specifically on the lateral properties is also motivated by the fact that the wake meandering is more pronounced in the transverse direction than in the vertical direction, with the ratio reflecting the turbulence intensities of the respective components (Yang and Sotiropoulos, 2019). The developed methodology also allows to extract a time series of peak wake deficit  $\Delta U$  value, however this is not discussed in this work.

## 2.2 Framework implementation: training data acquisition

The simulation environment enables modeling the operation of a given turbine at any location within the wind farm layout, capturing wake impingement effects from multiple turbines simultaneously. While this aspect plays a key role during testing, training is limited to interactions between two devices located on the farm border: a first-row wake ‘emitter’ and a second-row wake ‘receiver’, spaced approx. 6 rotor diameters apart. The role of the ‘receiver’ is to provide the turbine response data for training. Four wind directions, representing four distinctive wake impingement scenarios as seen from the front of the rotor, are defined as follows: a) fully impinged, turbine directly downstream from the closest neighbour; b) partially impinged, wake impacting the left side of the rotor; c) partially impinged, wake impacting the right side of the rotor; d) no impingement. The wind direction differs by 5 degrees between the fully and partially impinged cases. This setup allows to clearly differentiate between the effects of full/partial wake impingement and standalone atmospheric turbulence. It ensures that only one wake is impacting the ‘receiver’ turbine; including multiple wakes would complicate the impingement effects and make it more challenging to define wake detection classes (see Sec. 2.4). The partial layout of the wind farm and the wind directions defining the four classes are shown in Fig. 3.

A dataset comprised of 1200 simulations is produced, with simulation parameters and run counts presented in Table 1. Ambient wind speed  $U_{amb}$  and ambient turbulence intensity  $I_{amb}$  values are varied to ensure that the simulated conditions

**Figure 3.** Simulated wind farm with highlighted locations of two turbines of interest and selected wind directions for the training process.

would represent a multitude of different offshore wind states. Each simulation consists of generating a unique wind field and  
 130 calculating the corresponding time series of instantaneous turbine response. Synthetic wind fields are acquired by generating  
 ambient turbulence boxes using the Mann spectral tensor model (Mann, 1994) and superimposing them with wakes generated  
 with the SGRE’s in-house implementation of the DWM model (Larsen et al., 2007). The version of the model used follows  
 the parametrisation suggested in the latest IEC standard (IEC, 2019). In its essence, the DWM model considers the wake as  
 a passive tracer being moved laterally and vertically by stochastic turbulence with a characteristic length of twice the rotor  
 135 diameter or larger. The turbine operation for the simulated conditions is calculated using the aeroelastic code BHawC. Since  
 ambient wind fields are acquired with the Mann turbulence model, the atmospheric conditions are assumed to be neutral (Mann,  
 1994). The presence of vertical wind shear is simulated using the wind profile power law, with the shear exponent value of 0.07  
 selected for all cases. Turbines are simulated with no yaw angle misalignment.

## 2.3 Framework implementation: wind sensing

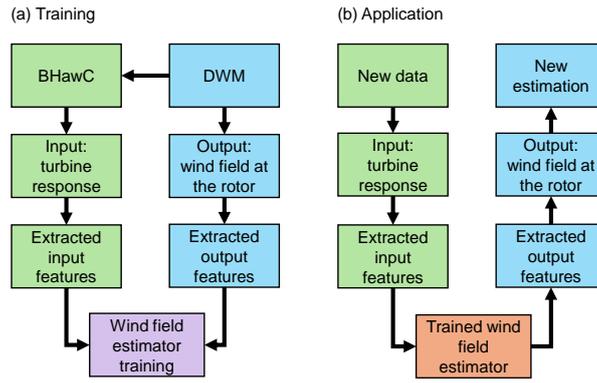

### 140 2.3.1 Wind sensing input and output data selection

Figure 4 illustrates training of the wind sensing model and demonstrates its application scheme. By providing a varied dataset  
 of turbine response time series and the corresponding wind field representations, the estimator ‘learns’ to approximate the wind  
 speed distribution at the rotor from the turbine sensor data.

The aeroelastic code provides access to an extensive set of turbine response signals, such as component accelerations or  
 145 generator speed. A conditional dependence analysis (readers further interested in the specific method used are referred to

**Table 1.** Training simulation subsets. For each wind direction, 300 simulations capturing all  $U_{amb}$  and  $I_{amb}$  combinations are performed.

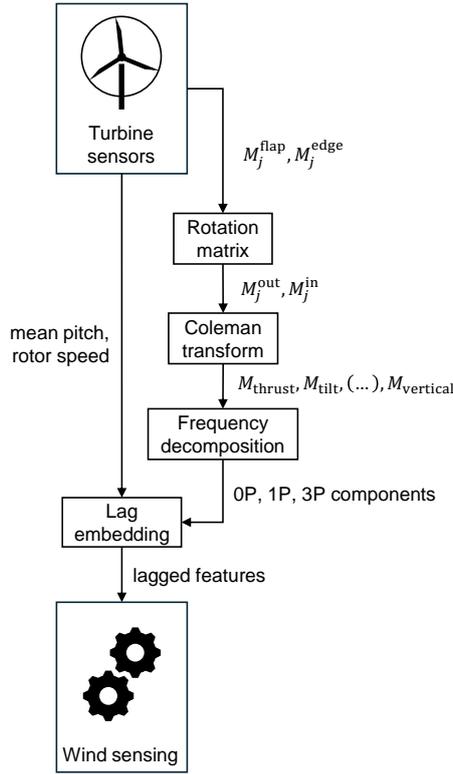

Wind direction [°]	Impingement case	$U_{amb}$ [m/s]	$I_{amb}$ [%]	# of simulations

4	Partial left			
14	Partial right			
45	None			
				Total: 1200

**Figure 4.** Simplified diagram visualising the flow of data during (a) training, (b) application of the wind sensing model.

(Azadkia and Chatterjee, 2021)) is undertaken to determine which data channels are best coupled with the variations in the flow. The algorithm tests different combinations of turbine signals, estimating the likelihood that wind speed can be deterministically predicted from them. The following combination with the strongest overall correlation to wind speed is identified and used in wind sensing: blade root bending moments in both the flap-wise and edge-wise direction; mean pitch across all three blades, simply calculated as  $\bar{\beta} = (\beta_1 + \beta_2 + \beta_3)/3$ ; rotor rotational speed  $\omega$ . Rotor azimuth angle and individual pitch angles are also extracted to use for transformations of other inputs.

The wind field is considered to be a three-dimensional Cartesian grid, with three axes: X representing streamwise distance, Y representing lateral distance, and Z representing vertical distance. To represent the wind speed distribution in the flow, each point on that grid stores the local values of three wind speed components  $U$ ,  $V$  and  $W$  that correspond to the spatial variation in the X, Y and Z axes, respectively. For this specific application, the wind field is represented with the spatial distribution of the longitudinal wind speed component  $U$ , as it is the one that is primarily impacted by wake deficit (Dimitrov et al., 2017). All models treat the wind field as a time series of YZ slices showing the chronological sequence of  $U$  distributions at the rotor plane.

**Figure 5.** Block diagram of the turbine response processing.  $M_j^{\text{flap/edge}}$ : flap/edge blade root bending moments,  $M_j^{\text{out/in}}$ : in/out of plane blade root bending moments,  $j$ : blade index,  $M_{\text{thrust/tilt}(\dots)\text{vertical}}$ : rotor loads. Detailed description in the text.

### 2.3.2 Wind sensing input processing

160 Selected turbine response time series are processed to extract the optimal features from the raw data. The processes described in this section are applied both during training and performance testing - they are an integral part of the data 'pipeline'. Figure 5 illustrates the transformations taking place in the feature extraction.

First, using the pitch signals, the edge- and flap-wise blade root bending moments are transformed to in- and out-of-plane coordinates. Performing the rotation between the two frames is calculated for a given blade  $j$  as follows:

$$165 \quad \begin{bmatrix} M_j^{\text{out}} \\ M_j^{\text{in}} \end{bmatrix} = \begin{bmatrix} \cos(\beta_j) & \sin(\beta_j) \\ -\sin(\beta_j) & \cos(\beta_j) \end{bmatrix} \begin{bmatrix} M_j^{\text{flap}} \\ M_j^{\text{edge}} \end{bmatrix} \quad (1)$$

where  $M_j^{\text{out}}$ ,  $M_j^{\text{in}}$  are out-of- and in-plane root bending moments, respectively;  $M_j^{\text{flap}}$ ,  $M_j^{\text{edge}}$  are flap and edge root bending moments, respectively;  $\beta_j$  is the instantaneous pitch angle.

Next, using the azimuth angle time series, the Coleman transformation (Coleman, 1943) is applied to the blade load data. It allows to effectively map the separate, rotary-frame bending moments from each blade onto a stationary frame of reference. As

170 a result, the dynamic response to the variation in the wind can be expressed with six variables describing the loads for an entire rotor:  $M_{\text{thrust}}$ ,  $M_{\text{tilt}}$ ,  $M_{\text{yaw}}$  (for out-of-rotor-plane movement),  $M_{\text{torque}}$ ,  $M_{\text{lateral}}$ ,  $M_{\text{vertical}}$  (for in-rotor-plane movement). These are referred to as *rotor loads*. The Coleman transformation is defined as follows:

$$C(\psi) = \begin{bmatrix} 1/3 & 0 & 0 \\ 0 & 2/3 & 0 \\ 0 & 0 & 2/3 \end{bmatrix} \begin{bmatrix} 1 & 1 & 1 \\ \cos(\psi) & \cos(\psi + \frac{2\pi}{3}) & \cos(\psi + \frac{4\pi}{3}) \\ \sin(\psi) & \sin(\psi + \frac{2\pi}{3}) & \sin(\psi + \frac{4\pi}{3}) \end{bmatrix} \quad (2)$$

where  $\psi$  is rotor azimuth angle. It is used to transform the blade loads as follows:

$$175 \begin{bmatrix} M_{\text{thrust}} \\ M_{\text{tilt}} \\ M_{\text{yaw}} \end{bmatrix} = C(\psi) * \begin{bmatrix} M_1^{\text{out}} \\ M_2^{\text{out}} \\ M_3^{\text{out}} \end{bmatrix} \quad (3)$$

$$\begin{bmatrix} M_{\text{torque}} \\ M_{\text{lateral}} \\ M_{\text{vertical}} \end{bmatrix} = C(\psi) * \begin{bmatrix} M_1^{\text{in}} \\ M_2^{\text{in}} \\ M_3^{\text{in}} \end{bmatrix} \quad (4)$$

where  $M_{1-3}^{\text{out}}$  is out-of-plane bending moment, and  $M_{1-3}^{\text{in}}$  is in-plane bending moment for blades indexed 1-3.

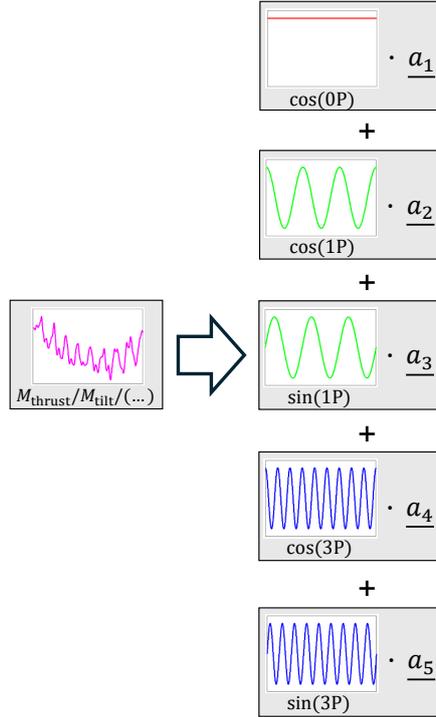

The rotor load time series are decomposed into its key frequency components. This process is visualised on Fig. 6. The five  
180 frequency components selected via a conditional dependence (Azadkia and Chatterjee, 2021) study are  $\cos(0P)$  for describing the mean signal value,  $\cos(1P)$  and  $\sin(1P)$  for describing the once-per-revolution variation, and finally  $\cos(3P)$  and  $\sin(3P)$  for describing the thrice-per-revolution variation. A sliding window function with a width of three revolutions is applied, projecting the original load time series onto each of the frequency components. The Fourier coefficients  $\underline{a}_1 - \underline{a}_5$  vectors obtained from these projections are stored, producing a coefficient time-series for each rotor load.

185 In order to capture the short-term temporal dependencies and patterns in time series of all wind sensing inputs, the features are embedded with their lagged values. For each sample in a time series, two additional features expressing the past value of the curve are added. These lagged features are obtained by shifting the time series by 4 and 8 seconds from the current time stamp. This effectively makes the estimation more stable and noise-resistant, as the wind slice is reconstructed with turbine response across several seconds. Specific lag values used are determined by testing the framework's performance with a few  
190 different configurations and choosing the one that gives the best overall results.

Due to implementing the transformations discussed in this section, using the turbine response data as wind sensing input effectively stops being a time series modelling task; instead, it becomes a time-independent regression task. Considering the entire feature extraction process, at each point in time, a 96-dimensional input vector captures and encodes the turbine's current operating state. Table 2 serves as a summary of these features.

### 195 2.3.3 Wind sensing output processing

The three-dimensional wind field representations are processed for data compression and efficient extraction of their key features for the best application in wind sensing. The wind field is represented with a sequence of YZ slices showing the U

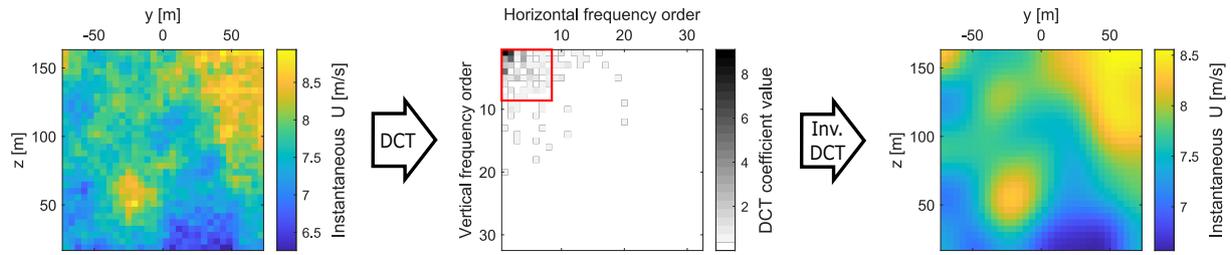

**Figure 6.** An example of rotor load time-series decomposition into frequency component coefficient vectors ( $\underline{a}_1 - \underline{a}_5$ ) capturing the contributions of each fourier mode at each point in time.

**Table 2.** A summary of features extracted from turbine response.

$\omega$	Lag embedding	3
		Total: 96

distribution at each point along the X axis. The spatial features of each slice are extracted, capturing the key characteristics of the wind field in a more compact form. The feature extraction is performed using the two-dimensional discrete cosine transform (DCT) (Ahmed et al., 1974). The result is similar to applying the principal component analysis; however, as opposed to this far more complex method, the DCT is a fixed transform and doesn't require any training. The DCT effectively converts the wind slice into a collection of cosine functions oscillating at different frequencies in both the vertical and horizontal directions. Each DCT coefficient corresponds to a specific frequency in the transformed domain and describes the contribution of each

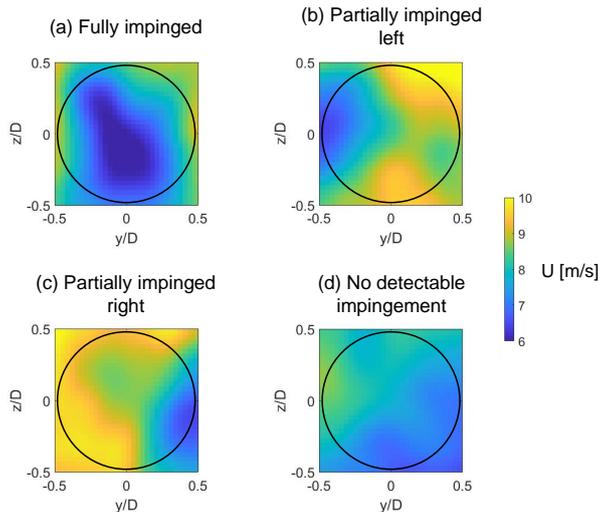

**Figure 7.** An example showing how the YZ slice of wind field (left) is transformed into a matrix of DCT components (centre) and then back into a truncated slice of wind through an inverse DCT (right). The red square indicates which DCT coefficients are stored for the implemented wind field representation.

frequency in the distribution of  $U$  on the given YZ slice. This concept, applied to an example wind field YZ slice, is presented on Fig. 7.

The lower-order frequencies primarily capture the large-scale structures of the field, while the higher-order are more associated with encoding smaller-scale, random fluctuations. It can be seen that the most significant values can be found in the upper left corner of the diagram, meaning the majority of flow distribution is being kept by the lower orders of DCT coefficients. For this reason, the key information on the flow can be easily extracted by storing only the lower orders and disregarding the higher order coefficients. Truncating the collection of DCT order coefficients essentially acts as a spatial low-pass filter. In this work, retention of 8 DCT coefficients is found to enhance computational efficiencies while allowing for good wind sensing accuracy. The right plot on Fig. 7 shows the effect of truncating the higher frequencies; it can be noticed how the wind slice is significantly 'smoothed', leaving only the major  $U$  fluctuations.

### 2.3.4 Training the wind sensing estimator

Having extracted the features from both the inputs and outputs, two thirds of data is used for the wind field estimator training, while the remaining 1/3 is put aside for generating wind field estimations for wake detector testing. The current implementation utilises a localised linear regression approach (Cleveland et al., 1988), where the estimator training is performed for multiple localised models. The preprocessed turbine response data is a time series of multidimensional input points, with each dimension representing a different feature (see Table 2). Two of these dimensions, namely unlagged  $\bar{\beta}$  and unlagged  $\omega$  (these being the key variables indicating the turbine's operating point), are used to define a projection plane, allowing input points to be mapped and binned by their values. A set of evenly spaced points on this plane is selected, and a local linear regression model is trained at each. Training data is assigned to models based on proximity within a defined radius, with overlapping points contributing to multiple estimators. Predictions for new inputs are made using the model nearest to their location on the projection plane. As a result, the training process builds functions that correlate the inputs to outputs only at a narrow section of data distribution. This eliminates the need to fit a global non-linear function that would singlehandedly need to describe the complex relationship between wind and turbine signals.

**Figure 8.** Example front-view YZ snapshot samples representing four classes defined for the neural network training. The rotor area indicated with a black circle.

## 2.4 Framework implementation: wake detection

Considering that wake detection can be essentially brought down to a classification task, we propose to deal with it by implementing a convolutional neural network. The overview of this deep learning technique can be found in Appendix A. The approach taken is to operate on the YZ snapshot samples (so-called 'front view'), showing the estimated instantaneous wind component  $U$  across the whole rotor plane, which makes it possible to easily differentiate between impinged and non-impinged conditions. To capture the different forms of wake impingement accurately, a total of four classes, directly relating to four wind directions used during the training data acquisition (see Sect. 2.2), are defined. These are as follows: a) fully impinged, turbine directly downstream from the closest neighbour; b) partially impinged left, wake impacting the left side of the rotor; c) partially impinged right, wake impacting the right side of the rotor; d) no detectable impingement. Figure 8 shows selected YZ samples being appropriate examples of each one of the four classes.

The turbine response time series from the remaining 400 simulations, set aside during the wind sensing estimator training, are now used for generating wind field estimations, allowing to build a new dataset for the CNN training. An extensive manual review of these wind fields allows for a following conclusion: in the available dataset, a clear, non-dissipated wake is only visible for lower values of the selected ambient wind speed range - typically up to 14-16 m/s, depending on the ambient turbulence intensity. The aim of the detector is to recognize (as robustly as possible) whether the turbine is most likely experiencing a wake impingement from a nearby machine, which is why the training data must be devoid of samples that would be arguable regarding which class they should be part of. With that in mind, the CNN is trained with data from simulations where the mean ambient wind speed  $U_{\text{amb}}$  is between 5 and 15 m/s, while maintaining the full range of turbulence intensity values (3%, 5%

**Table 3.** Implemented CNN architecture.

Layer #	Name	Details
1	Image input	Layer size = 32x32
2	Convolution	8 kernels with size = 3
3	Batch normalisation	
4	ReLU	
5	Max pooling	Pool size = 2, stride = 2
6	Convolution	16 kernels with size = 3
7	Batch normalisation	
8	ReLU	
9	Max pooling	Pool size = 2, stride = 2
10	Convolution	32 kernels with size = 3
11	Batch normalisation	
12	Fully connected	
13	Output normalisation	Type: softmax
14	Classification	Layer size = 4

245 and 7%). The YZ 'snapshot' samples are taken every 10 seconds from the available training data, resulting in 11,200 labelled samples.

The implemented CNN architecture is presented in Table 3. The input layer has the same resolution as the YZ slice of estimated wind. The three convolution layers have iteratively increasing number of kernels, allowing the network to progressively learn more complex features at deeper levels (Goodfellow et al., 2016). A batch normalisation layer is added after each of  
250 the convolution layers for the sake of normalisation of weight gradients and neuron activations, thus speeding up the training process. Two max pooling layers reduce the spatial size of the feature maps. The activation function is selected as the Rectified Linear Unit (ReLU). The final three layers transform the learned features into predictions, connecting all of the neurons, normalising outputs into probabilities and performing final classification. An extended description of the layers used can be found in Appendix A. The optimal hyperparameter values are chosen based on trial-and-error, monitoring the CNN accuracy through  
255 integrated testing.

The training is conducted using Matlab's Deep Learning Toolbox. 90% of the available labelled data (10,080 samples) is used for training. The samples are shuffled before the training process, as well as after each one of the four epochs. The training is repeated several times to make sure there are no deviations. The remaining 10% of samples are used for an integrated testing cycle, which automatically occurs after the training is complete. Figure 9 shows its results in the form a confusion matrix.  
260 As can be observed, the main source of error are the misclassifications between the 'Fully impinged' and 'No detectable

True Class	Fully impinged	229	6		23	88.8%	11.2%
	Partially impinged left	3	277		4	97.5%	2.5%
	Partially impinged right	13		277	7	93.3%	6.7%
	No detectable impingement	27	2	2	250	89.0%	11.0%
		Fully impinged	Partially impinged left	Partially impinged right	No detectable impingement		
		Predicted Class					

**Figure 9.** Confusion matrix for the integrated testing of trained CNN. Each row represents the instances of a true class, whereas each column represents the instances of a predicted class. As a result, the values in diagonal (blue) and off-diagonal (orange) cells correspond to correct and false classifications, respectively. Percentages of correct (blue) and false (orange) classifications within each true class shown on the right.

impingement' classes. This phenomenon is further investigated in Sect. 3 and 4, where the performance of each of the models is analyzed in more detail under a variety of conditions.

## 2.5 Framework implementation: wake characterisation

The final part of the developed framework is the identification of the key wake parameters in cases where a clear wake im-  
265 ppingement is detected. This is undertaken by scanning for the characteristic velocity deficit shape in the appropriate wind field representations.

### 2.5.1 Two-dimensional Gaussian fitting

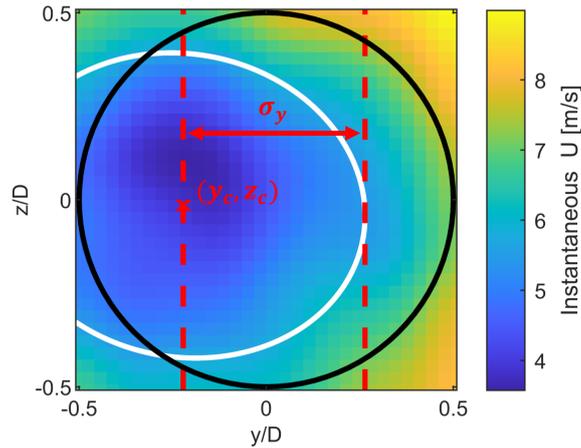

The 'tracking' of wake position and width is achieved by implementing a two-dimensional Gaussian fitting scheme based on a least squares algorithm. This method is a commonly used solution in the literature for the dynamic wake properties analysis  
270 (Abkar and Porté-Agel, 2015; Trujillo et al., 2011; Conti et al., 2020). First, the wake deficit is defined for every sample as follows:

$$U_{\text{def}}(y, z) = U(y, z) - U_{\text{amb}} \quad (5)$$

where  $U(y, z)$  is the instantaneous wind speed distribution across the YZ plane, and  $U_{\text{amb}}$  is the mean ambient wind speed value.

275 A general, bivariate two-dimensional Gaussian function for spatial variables of  $y$  and  $z$  is expressed as:

$$f_{\text{bivariate}}(y, z) = \frac{A}{2\pi\sigma_y\sigma_z\sqrt{1-\rho^2}} \exp \left[ -\frac{1}{2(1-\rho^2)} \left( \frac{(y-y_c)^2}{\sigma_y^2} - \frac{2\rho(y-y_c)(z-z_c)}{\sigma_y\sigma_z} + \frac{(z-z_c)^2}{\sigma_z^2} \right) \right] \quad (6)$$

**Figure 10.** An example of a bivariate two-dimensional Gaussian fit performance applied to a YZ wind field sample. Rotor outline marked with black line; fitted wake ellipse marked with white line; fitted wake centre at  $(y_c, z_c)$  marked with red x sign; the extent of fitted lateral half-width  $\sigma_y$  marked with dashed lines.

where  $A$  is amplitude equal to height of the peak;  $\sigma_y$  and  $\sigma_z$  are standard variations along Y and Z axis, respectively;  $\rho$  is correlation coefficient between function's spread in Y and Z;  $y_c$  and  $z_c$  are means along Y and Z, respectively.

The time series of wake deficits from Eq. (5) is fitted to Eq. (6) through a Levenberg-Marquadt non-linear least squares algorithm implemented with Matlab's Optimization Toolbox. Fitted Gaussian parameters are then used to identify wake properties: the function peak at  $(y_c, z_c)$  can be interpreted as position of wake centre;  $\sigma_y$  and  $\sigma_z$  describe the spread of wake along Y and Z axis, respectively;  $\rho$  can be used to calculate the lengths of semi-minor and semi-major axis of the wake ellipse, as well as their orientation with respect to the YZ axes. The initial guess for  $\sigma_y$  and  $\sigma_z$  is defined as half of rotor diameter  $D$  in order to best reflect the typical width expected of a wake.

As explained earlier, the framework outputs refer solely to the lateral wake characteristics, which are expressed by the variation on the Y axis. Out of all fitted parameters, only two are required to describe the lateral wake variation:  $y_c$  and  $\sigma_y$ . To parametrically represent the size of the wake deficit, it is assumed that the lateral half-width corresponds to standard deviation in the Y direction. With that in mind, the wake extends laterally for  $2\sigma_y$ , with the fitted centre  $y_c$  in the middle. Figure 10 shows an example of the bivariate two-dimensional Gaussian fit applied on an YZ wind field sample, with the key characterised properties indicated.

### 2.5.2 Filtering with moving average window

The lateral wake half-width and centre position time series are smoothed using a moving average filter to reduce high-frequency noise from sample-by-sample variability, while preserving slower variations associated with wake meandering. This way, the

ultimate characterised wake properties time series  $y_c^{\text{filt}}$  and  $\sigma_y^{\text{filt}}$  are defined as follows:

$$295 \quad \begin{bmatrix} y_c^{\text{filt}}(t) \\ \sigma_y^{\text{filt}}(t) \end{bmatrix} = \frac{1}{\tau} \int_{t-\tau}^t \begin{bmatrix} y_c(t) \\ \sigma_y(t) \end{bmatrix} dt \quad (7)$$

The variable  $\tau$  stands for window size in seconds which is calculated separately for every wind field in a following manner:

$$\tau = \frac{L_{\text{meand}}}{\overline{U}_{\text{hh}}} \quad (8)$$

where  $L_{\text{meand}}$  is the characteristic meandering length equal to two rotor diameters (value corresponding to findings from the literature, used in several wake models like the DWM itself (Larsen et al., 2007)) and  $\overline{U}_{\text{hh}}$  is the mean  $U$  value at the hub height.

300 It should be noted that in this method of moving average filtering, the averaging window is not centred at the current sample; instead, the window extends from the past sample occurring  $\tau$  seconds ago to the current sample. As a result, the filtered wake centre and lateral half-width time series experience a small lag of  $\tau/2$ .

### 2.5.3 Treatment of non-impinged samples

To satisfy the assumption that wake characterisation should not be performed for wind samples without clear impingement, the  
305 filtered wake properties are treated for a given time stamp  $i$  as follows:

$$y_c^{\text{filt}}(i), \sigma_y^{\text{filt}}(i) = \begin{cases} y_c^{\text{filt}}(i), \sigma_y^{\text{filt}}(i), & \text{if class}(i) = \text{fully/partially impinged} \\ \text{NaN}, & \text{if class}(i) = \text{no detectable impingement} \end{cases} \quad (9)$$

The assignment of NaN values ensures that the samples identified as non-impinged are not being represented with a two-dimensional Gaussian wake in the framework output.

## 3 Results

### 310 3.1 How is the performance evaluated

The framework's performance is evaluated with 3600 new simulations divided into 10 subsets. The configurations with number of runs is shown in Table 4. Each simulation is paired with the corresponding turbine response. All simulations are performed for one 'receiver' turbine, which is more centrally located within the wind farm compared to the machine used for the training; by doing so, it experiences different types of impingement for different wind directions. Both qualitative and quantitative  
315 performance analysis is conducted for each of the three constituent models.

In this work, the reference for quantitative analysis of the models' accuracy is the collection of the raw DWM-generated wind fields. Wind sensing accuracy analysis is a straightforward calculation of Root Mean Square Error (RMSE) between the  $U$  data points in simulated wind fields and the estimated equivalents. A reference for wake detection accuracy analysis is created via a new classifier trained analogically to the process described in Sec. 2.4, with the only difference being that the training

**Table 4.** Testing simulation subsets. For each  $U_{\text{amb}}$  and  $I_{\text{amb}}$  combination, 360 simulations capturing full wind direction spectrum are performed.

$U_{\text{amb}}$ [m/s]	$I_{\text{amb}}$ [%]	Wind direction [°]	# of simulations
5, 7, 9, 11, 13, 15	5	1-360 (step size 1)	2160
10	3, 5, 7, 9		1440
			Total: 3600

320 dataset is derived from simulated wind fields, not the estimated ones. Without the bias from the wind field reconstruction, this classifier achieves approx. 99% accuracy under integrated testing. As such, its classifications across all 3600 raw wind fields (with the wind sensing step not performed) are thus taken to be the 'ground truth' reference. Finally, the reference for wake characterisation is obtained by processing a raw simulated wind field: a two-dimensional Gaussian is fitted, moving average filtering is applied, and 'non-impinged' wind slice samples are removed analogically to the process described in Sec. 2.5.

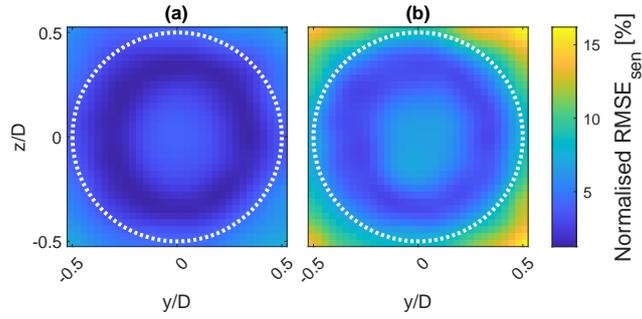

325 The wind sensing accuracy is first analysed by plotting the RMSE across the YZ plane for two example simulations from the testing dataset presenting low and high ambient turbulence. This is shown in Sec. 3.2. The wind-direction-dependent wind sensing and wake detection performance is then analysed via a sensitivity study to  $U_{\text{amb}}$  and  $I_{\text{amb}}$ , comparing these models' mean accuracy across the entirety of 10 subsets described above. This is discussed in Sec. 3.3. Sec. 3.4 presents detailed wake characterisation results. This is achieved by visualising framework's performance across selected wind fields from the testing  
330 dataset, followed by computing quantitative performance metrics of wake characterisation.

### 3.2 Wind sensing: YZ-wise accuracy

Figure 11 compares the YZ-plane distribution of the wind sensing RMSE for low (a) and high turbulence intensity (b). This distribution is obtained by calculating  $\text{RMSE}_{\text{sen}}$  at every YZ location over the full duration of the simulation  $n_t$ :

$$\text{RMSE}_{\text{sen}}(y, z) = \sqrt{\frac{1}{n_t} \sum_{i=0}^{n_t} (U_i^{\text{est}}(y, z) - U_i^{\text{DWM}}(y, z))^2} \quad (10)$$

335 where  $U_i^{\text{est}}(y, z)$  and  $U_i^{\text{DWM}}(y, z)$  are the YZ-specific  $U$  at time  $i$  for estimated and DWM wind field, respectively. Both plots show the error to be higher at the rotor centre and in the corners outside the rotor area. The high  $I_{\text{amb}}$  plot reports significantly higher RMSE, with the critical corner area reaching approximately twice the value of the low-turbulence case. The ring-like pattern of area with lowest error (dark blue in the plot) is repeated across all wind conditions, plots for which are not shown here for brevity.

**Figure 11.** Wind sensing RMSE plotted across YZ slice, normalised by the corresponding  $U_{amb}$  value of 10 m/s. (a):  $I_{amb} = 3\%$ ; (b):  $I_{amb} = 9\%$ . Rotor outline marked with dotted white line.

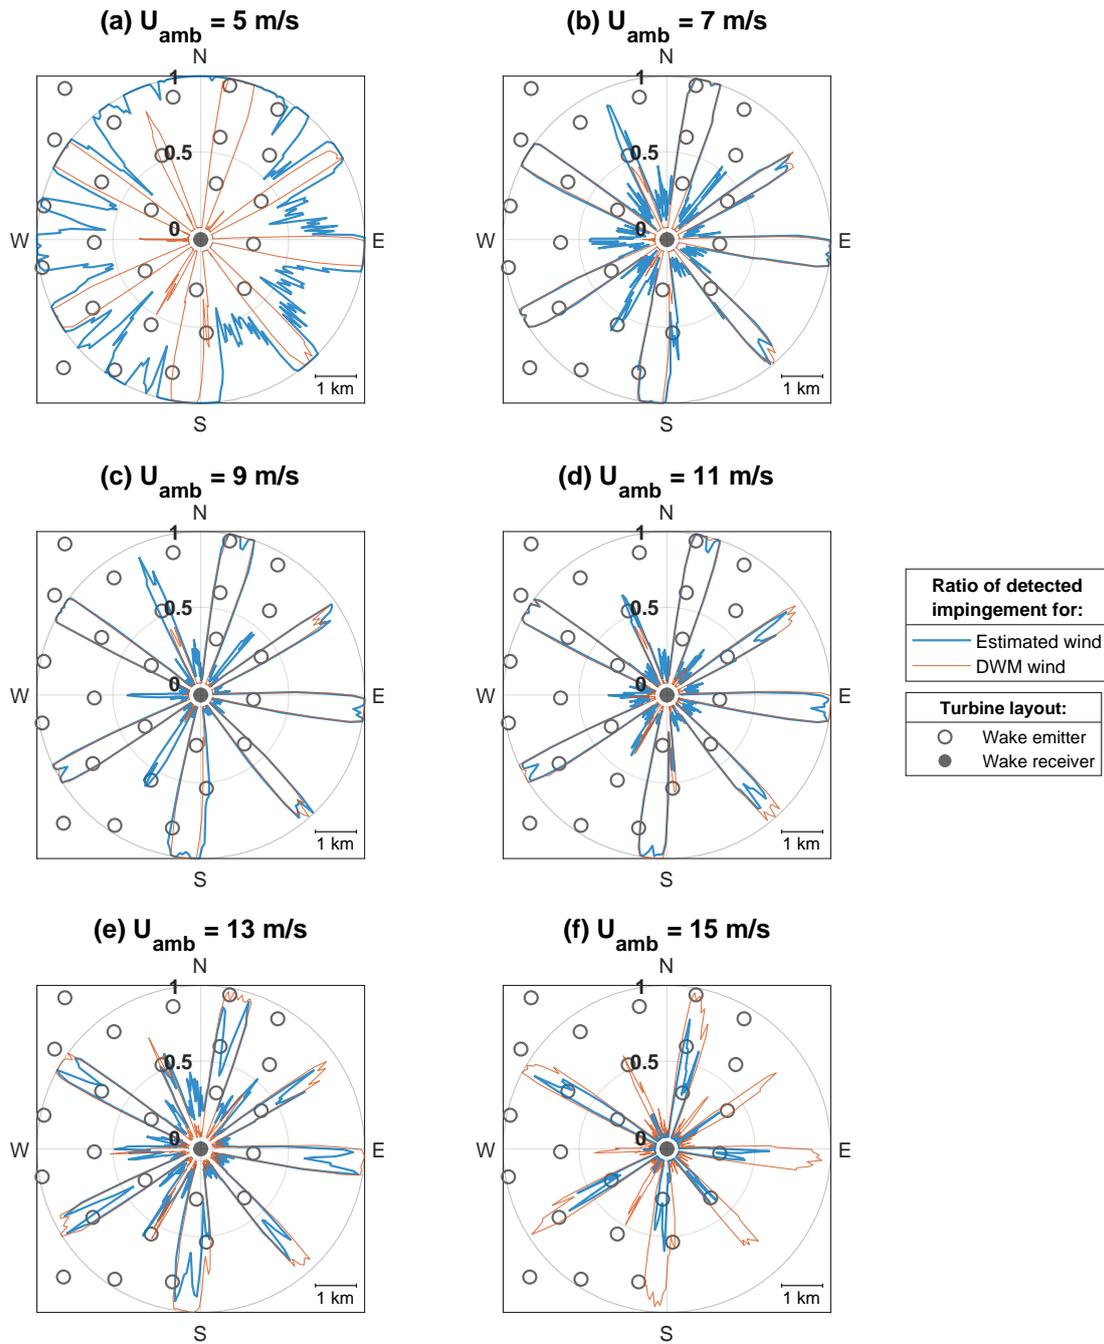

**Table 5.** A comparison of performance metrics in wind sensing and wake detection under varying  $U_{amb}$  and  $I_{amb}$ .  $\overline{\text{RMSE}}_{\text{sen}}$  is normalised by the corresponding  $U_{amb}$  value.

$U_{amb}$ [m/s]	$I_{amb}$ [%]	Normalised $\overline{\text{RMSE}}_{\text{sen}}$ [%]	RMSE <sub>det</sub>
5	5	6.7	0.67
7	5	3.9	0.18
9	5	3.3	0.14
11	5	3.1	0.11
13	5	2.7	0.17
15	5	2.3	0.23
10	3	2.2	0.07
10	5	3.1	0.20
10	7	4.3	0.19
10	9	5.6	0.30

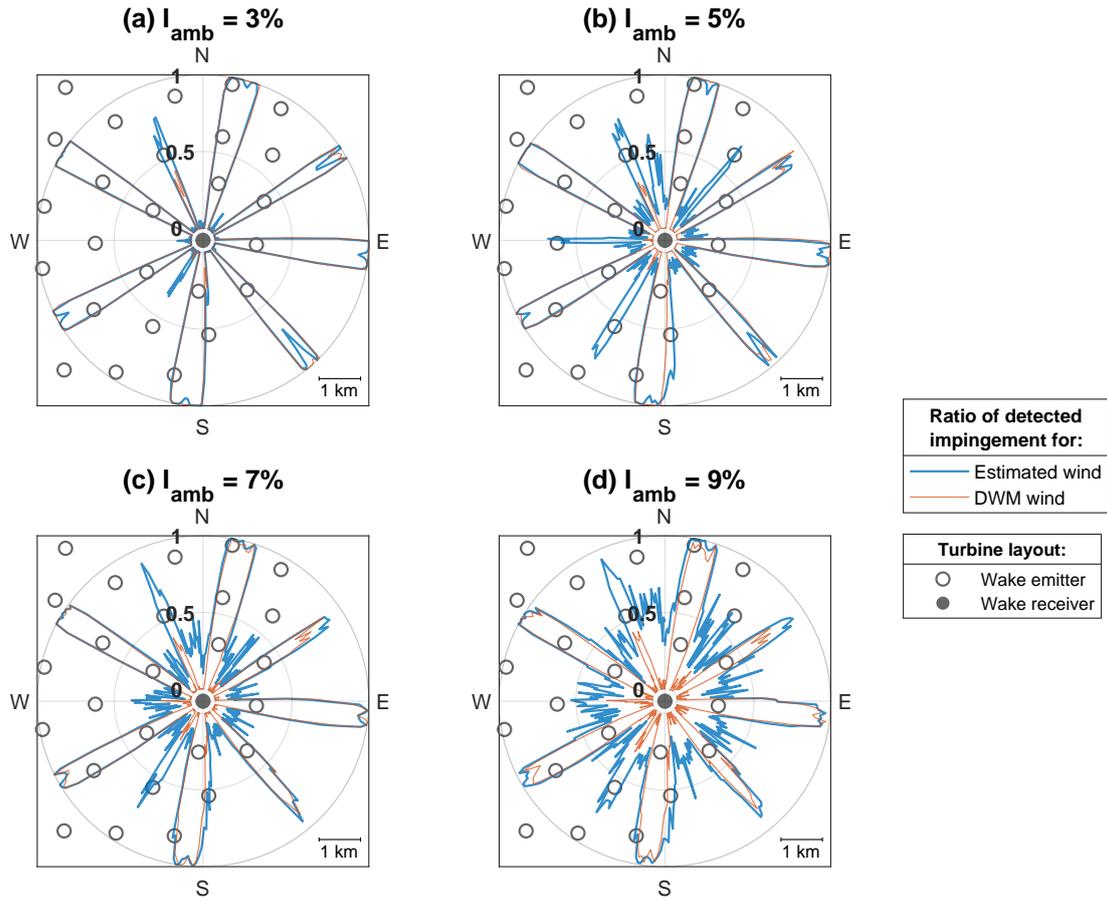

### 340 3.3 Wind sensing and wake detection: ambient conditions sensitivity study

For all 3600 simulations, the YZ distributions of wind sensing RMSE (such as the examples in Fig. 11) are averaged across the entire rotor plane to obtain a single simulation-specific mean value. Furthermore, to check how the RMSE changes with wind conditions, mean  $\overline{\text{RMSE}}_{\text{sen}}$  values averaging all 360 simulations with the same  $U_{amb}$  and  $I_{amb}$  are calculated. These values are presented in Table 5.

345 For each of the 3600 simulations, the proportion of samples (YZ wind slices at a point in time) classified as a clear wake impingement (either 'fully impinged', 'partially impinged left', or 'partially impinged right'), is calculated. These simulation-specific impingement ratios are compared to their equivalents in the reference established by the 'ground truth' classifier (see

**Figure 12.** The wake detection model performance tested under a full wind direction range for six  $U_{amb}$  values between 5 and 15 m/s.  $I_{amb} = 5\%$  for all cases. The radial values in blue and orange indicate impingement ratio for a given wind direction. Wind farm layout shown in the background.

**Figure 13.** The wake detection model performance tested under a full wind direction range for four  $I_{amb}$  values between 3% and 9%.  $U_{amb} = 10$  m/s for all cases. The radial values in blue and orange indicate impingement ratio for a given wind direction. Wind farm layout shown in the background.

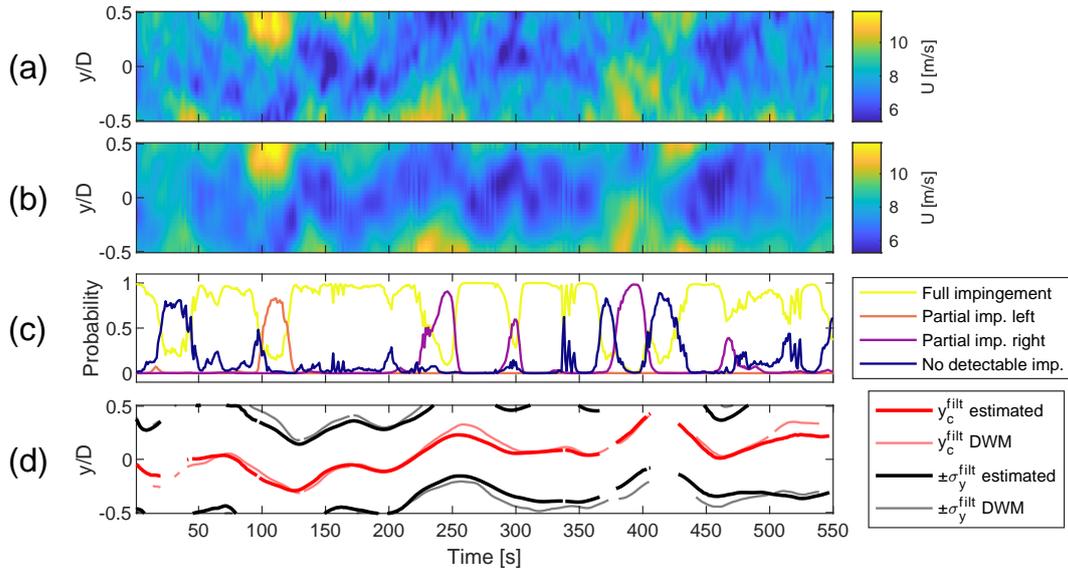

Sec. 3.1). This provides a quantitative measure of the wake detection error for a given wind direction. A single wake detection  $RMSE_{det}$  value is calculated across the entire wind direction range, for each of the 10  $U_{amb}$  and  $I_{amb}$  combinations:

$$350 \quad RMSE_{det} = \sqrt{\frac{1}{n_{wd}} \sum_{i=0}^{n_{wd}} (r_i^{est} - r_i^{DWM})^2} \quad (11)$$

where:  $n_{wd}$  is number of wind directions,  $r_i^{est}$  is simulation-specific estimated impingement ratio,  $r_i^{DWM}$  is simulation-specific impingement ratio from the raw DWM wind reference.

These values are presented in the rightmost column of Table 5. Figures 12 and 13 show the impingement ratios (both the DWM 'ground truth' and estimated) across the full range of wind directions and under varying  $U_{amb}$  and  $I_{amb}$  conditions.

355 For each  $U_{amb}$  and  $I_{amb}$  combination, the plot displays the wind farm layout with the wake 'receiver' turbine in the centre. Polar values visualise the proportion of samples for a given wind direction classified as flow with a clear wake deficit. These

**Figure 14.**  $U_{amb} = 10$  m/s,  $I_{amb} = 9\%$ , fully impinged. (a) Horizontal slice of the simulated wind field at the hub height. (b) Horizontal slice of the estimated wind field at the hub height, obtained with the wind sensing model. (c) Classification scores obtained with wake detection model. (d) Fitted wake properties obtained with wake characterisation model next to the reference fitted on the raw DWM wind.

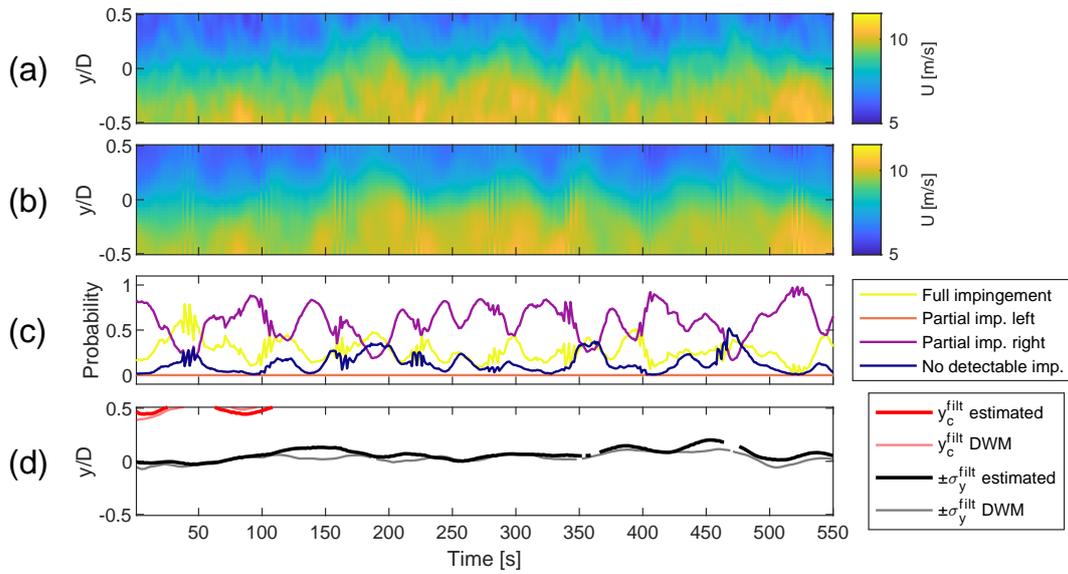

proportions are shown as radial values between 0 (all simulation samples identified as 'no detectable impingement') and 1 (all simulation samples identified as 'full impingement', 'partial impingement right' or 'partial impingement left').

### 3.4 Wake characterisation: time-wise accuracy

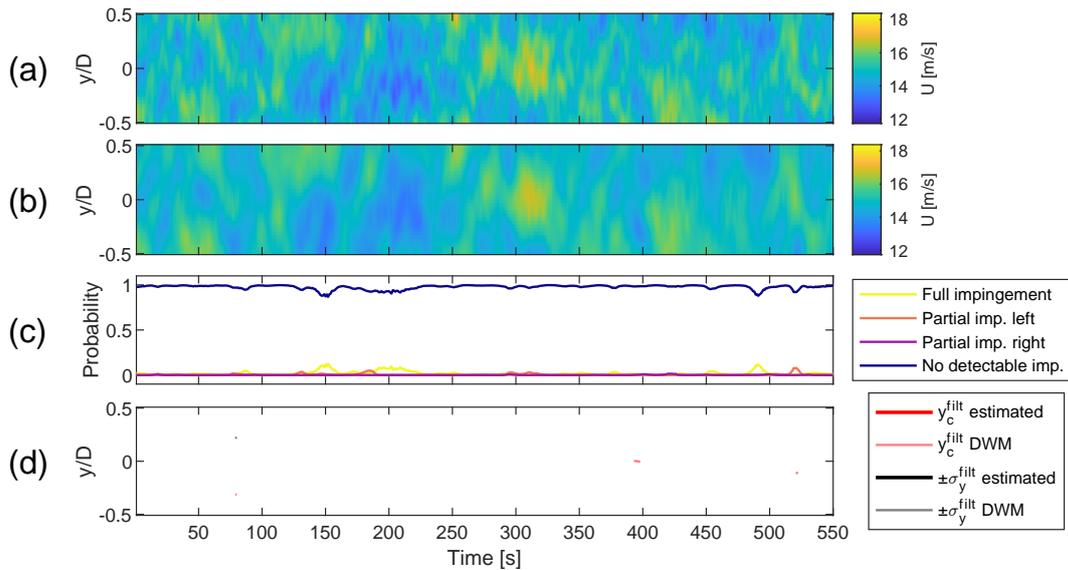

360 Figures 14 to 17 provide a detailed performance analysis of the framework across four example wind fields. In each figure, plots (a) and (b) show hub-height horizontal slices of the simulated and estimated  $U$  distributions, respectively. The (c) plots display direct wake detection outputs from the CNN's classification, assigning a value between 0 and 1 to each of the four classes, representing the probability of a sample depicting a corresponding wake impingement case. These probabilities sum up to 1, so a near-perfect class representation has a confidence score near 1, with the other three values near 0. The (d) plots  
 365 present the outputs of wake characterisation, showing the fitted and filtered lateral wake properties against the DWM reference (see Sec. 3.1).

Figures 14 and 15 compare the performance under high and low  $I_{amb}$ , respectively. They also exhibit different degrees of wake-rotor overlap, allowing to investigate both full and partial impingement scenarios. Figures 16 and 17 show the performance in a scenario with no turbines upstream from the 'receiver' device. They show the effects of operating under low and  
 370 high  $U_{amb}$  conditions, respectively.

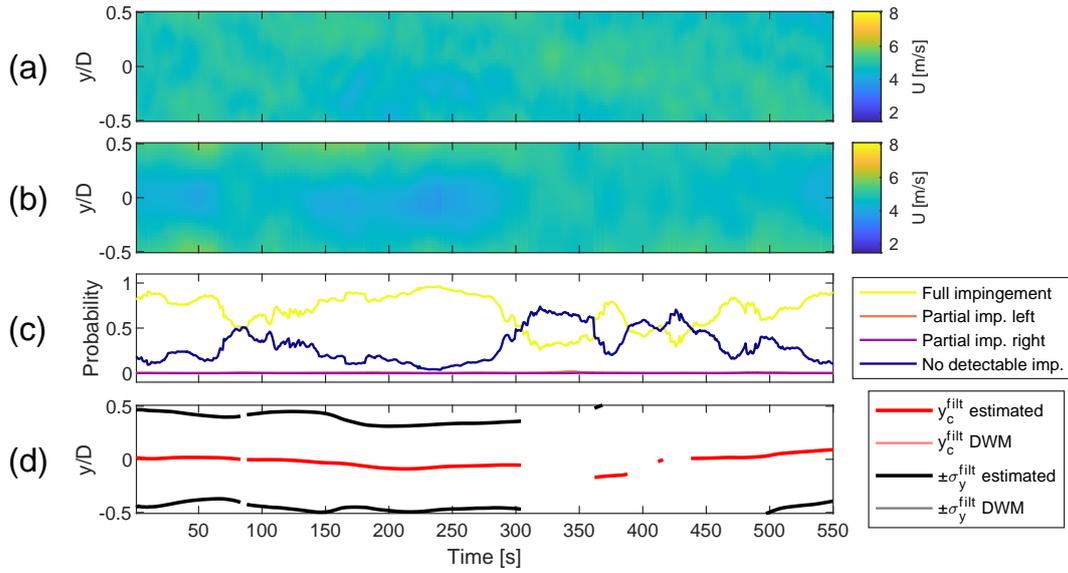

Quantitative metrics for wake characterisation accuracy are computed as shown in Eqs. 12 and 13. Using the reference derived from raw DWM wind fields (see Sec. 3.1), RMSE is calculated over the time series of both lateral wake centre and

**Figure 15.**  $U_{amb} = 10$  m/s,  $I_{amb} = 3\%$ , partially impinged. (a) Horizontal slice of the simulated wind field at the hub height. wake width. Samples classified as 'no detectable impingement', containing NaN values as discussed in Sec. 2.5, are excluded from the calculation.

$$375 \quad \text{RMSE}_{\text{char}}^{y_c} = \sqrt{\frac{1}{n_t} \sum_{i=0}^{n_t} (y_{c,i}^{\text{filt}}(\text{est}) - y_{c,i}^{\text{filt}}(\text{DWM}))^2} \quad (12)$$

$$\text{RMSE}_{\text{char}}^{\sigma_y} = \sqrt{\frac{1}{n_t} \sum_{i=0}^{n_t} (\sigma_{y,i}^{\text{filt}}(\text{est}) - \sigma_{y,i}^{\text{filt}}(\text{DWM}))^2} \quad (13)$$

where:  $n_t$  is the simulation duration;  $y_{c,i}^{\text{filt}}(\text{est})$  and  $\sigma_{y,i}^{\text{filt}}(\text{est})$  are estimated  $y_c^{\text{filt}}$  and  $\sigma_y^{\text{filt}}$  at time  $i$ , respectively;  $y_{c,i}^{\text{filt}}(\text{DWM})$  and  $\sigma_{y,i}^{\text{filt}}(\text{DWM})$  are  $y_c^{\text{filt}}$  and  $\sigma_y^{\text{filt}}$  at time  $i$  from the reference fitted on raw DWM wind, respectively.

380 Table 6 shows the wake characterisation RMSE calculated for example wind fields exhibiting full/partial wake impingement, under high/low  $I_{amb}$ . For brevity, only two of these wind fields are visualised in Figs. 14 and 15. Wind fields in which the DWM reference shows primarily 'no detectable impingement' - such as those in Figs. 16 and 17 - are excluded from the RMSE analysis, as the reference wake characterisation contains mostly NaN values.

**Table 6.** Performance metrics for wake characterisation.

Partial	10	9	0.1	0.1
Partial	10	3	0.03	0.05

## 4 Discussion

### 385 4.1 Evaluation methods

The reference for wake detection is based on the classifications from a detector trained with raw simulated wind fields. This allows to consider the effects of varied wake dispersion under different ambient conditions, and arguably fits this analysis better than a general impingement definition based strictly on inflow angle. Indeed, to the best of author’s knowledge, there isn’t a widely-recognised definition of ‘wake impingement’ (e.g. by means of reduced power output) that could be used here instead.

390 Wake characterisation accuracy is evaluated by processing the raw DWM wind with the methods from Sec. 2.5, thus extracting reference wake properties. This approach is preferred over taking the ‘ground truth’ from the meandering wake centres applied internally in the DWM model, as turbulent fluctuations in the synthetic wind field — along with additional imposed turbulence - can cause the actual wake experienced by the turbine to deviate from the calculated position. Moreover, this method naturally accommodates the interaction of multiple, combined wakes. A reference derived by fitting a Gaussian profile on a  
 395 simulated wind is used in other studies (Lejeune et al., 2022).

However, it should be noted that using the same methodology to perform estimations and establish reference both, with the only major difference being the source of the wind field, carries a bias. This is especially relevant for calculated wake characterisation metrics; calculated RMSE values could be expected to increase with the use of different reference approach. In future work, we aim to address this by validation with higher fidelity simulations and wind field data.

### 400 4.2 Framework performance

#### *Wind sensing*

Although there are minor discrepancies for specific wind conditions, the developed wind sensing model presents generally good performance with low error between reference and estimated values. Fig. 11 reveals that the wind field reconstruction quality is highest at the radial distance of approx. half of the rotor radius. This is likely due to the flow impacting the mid-blade region having the largest influence on the root bending moments. The YZ locations outside of the rotor plane yield the highest  
 405 RMSE due to blade-sensors being unable to react to the flow fluctuations from that region meaningfully. Figures 14 and 15 show that major flow fluctuations are well captured in the estimated wind field representations. Some smoothing occurs for

smaller-scale fluctuations, but this does not pose a major problem for wake detection. In fact, the attenuation of less significant turbulent eddies allows the wind sensing procedure to act as a spatial filter, focusing on larger flow structures like a wake deficit.

410 The sensitivity study from Sec. 3.3 shows that the normalised  $\overline{\text{RMSE}}_{\text{sen}}$  rises with increasing  $I_{\text{amb}}$ , which can be attributed to the higher flow complexity in more turbulent wind. The cause for higher error in low  $U_{\text{amb}}$  cases is investigated in Figure 17. The wind field reconstruction shows a minor  $U$  deficit that is not present in the simulated wind field, which is identified by the CNN as a wake impingement. This phenomenon occurs for the majority of wind directions at  $U_{\text{amb}} = 5$  m/s (see Fig. 12 (a)), which in turn is the cause for high respective wake detection RMSE captured in Table 5. Looking at the high  $U_{\text{amb}}$  case at Fig.

415 17, it is apparent that a more heterogeneous wind field effectively disperses such anomalies. This emergence of ‘fake’ wakes under low wind speed conditions is likely a result of the training dataset composition, 75% of which shows wake impingement, leaving only 25% for purely ambient turbulence cases. Using a single wind sensing estimator across these cases introduces a bias, as the model is predominantly trained on wake impingement conditions. The misclassification between ‘Fully impinged’ and ‘No detectable impingement’ is quantified by the confusion matrix Fig. 9.

#### 420 *Wake detection*

Examining both Fig. 12 and 13, most plots show the wakes generated by upstream turbines to be correctly identified for the corresponding wind directions at the ‘receiver’ turbine. There is a distinct difference in the proportion of samples identified as a wake depending on the distance between the ‘emitter’ and ‘receiver’. For turbines further away, the proportion of detected impingement is lower due to the wake losing its distinctive shape over a longer distance and interacting with the turbulent atmospheric boundary layer for a longer time. This relationship is evident in both the number of ‘impingement’ samples per simulation (length of the blue/orange peak) and the number of wind directions for which the wake is detected (width of the blue/orange peak).

425

The superposition of wakes does not seem to have any effect on wake detection performance. Wakes from eastern turbines (a single machine upstream) do not give substantially different wake detection results than wakes from deep inside the wind farm to the west. It appears that the primary aspect that decides the wake detection performance is the distance between the ‘receiver’ and ‘emitter’ machines. It is likely a consequence of limiting the training data to one pair of ‘emitter’-‘receiver’ turbines at a fixed distance.

430

As shown in Table 5, the wake detection RMSE largely follows the trends from the wind sensing RMSE. This is expected, as one model uses the outputs from the other. The highest error across all cases is reported for ambient wind speed of 5 m/s, which is due to the wind sensing anomaly described above. The wake detection is progressively more accurate with increasing  $U_{\text{amb}}$  (attributed to dispersion of the anomaly), until the RMSE begins to rise above 11 m/s. Visual inspection of Fig. 12 (ef) reveals this is a consequence of increased estimation-reference mismatch at the wind directions with high impingement ratio. These wind speeds usually correspond to above-rated operation, where the wakes are less pronounced due to decreased thrust, likely making them more difficult to detect. The wake detection RMSE rises with increasing  $I_{\text{amb}}$  value; the plots at Fig. 13 show that

440 the main source of the error is an increasing ‘noise’ of some wake impingement detected for all of the wind directions. This is expected, as more turbulent wind fields contain more large-scale ambient eddies that could be identified as a wake.

The sample-by-sample classification is presented at (c) plots in Figs. 14 to 17. The CNN's output aligns with the respective wind slice samples; for example, when wake meanders from centre to the Y-positive part of the snapshot, the highest probability transitions from 'Full impingement' to 'Partial imp. left'. This indicates that the instantaneous wake position can be, at least to  
445 some extent, tracked even without a dedicated wake characterisation model.

#### *Wake characterisation*

Figures 14 and 15 show the sample-by-sample wake deficit characterisation for two example wind fields. Visual comparison between the simulated wind field at (a) plots and characterised wake at (d) plots shows that the wake behaviour is appropriately captured in both cases. The estimated wake properties fit the reference values reasonably well. The time series of fitted wake  
450 centre and lateral border are near-continuous for lower  $I_{amb}$ , while higher  $I_{amb}$  yields a characterisation with few gaps. That is due to the removal of samples classified as 'No detectable impingement' class, which happens more often when the deficit shape is distorted by increased ambient turbulence. Table 6 brings further insight, showing quantitative characterisation accuracy metrics for full/partial impingement under low/high  $I_{amb}$ . As expected, higher turbulence causes the estimated wake properties to diverge more from the reference, thus increasing the RMSE. For all wind fields, the error is higher for  $\sigma_y$  than for  $y_c$ , likely  
455 due to the wake centre being more easily identified by the least squares algorithm (it's simply the area of lowest value). Error comparisons between full and partial impingement reveal mostly similar values, the only outlier being  $RMSE_{char}^{y_c}$ , at  $I_{amb} = 9\%$ , where the partial wake error is twice that of the full wake. This is a logical outcome, given the increased difficulty of characterisation when wake meandering motion is strong and centre is outside the YZ snapshot.

Figure 16 (d) shows how the 'fake' wake anomaly discussed above results in a characterisation performed on ambient  
460 turbulence. This effect is gone when the  $U_{amb}$  is higher (see Fig. 17 (d)), which is why the characterisation is missing for the entire wind field except few isolated samples.

### **4.3 Applicability**

Overall, the presented performance shows that the developed methodology is a promising solution to the challenging problem of generalised wake impingement estimation. The less accurate wake detection for  $U_{amb}$  values of 5 and 15 m/s is less critical  
465 after the consideration of the specific application of this work. Firstly, at  $U_{amb} = 5$  m/s the turbine is usually close to its cut-in wind speed (Carrillo et al., 2013), meaning that for many cases, applying flow control would not be necessary. Secondly, the wind farm flow control brings the largest benefits for below-rated operation, where due to higher energy extraction and lower wind, the wakes are more pronounced (Scott et al., 2024). These conditions align with the scenarios where the framework demonstrates optimal performance. The wind speeds above 13 m/s (where the framework performance deteriorates) are gener-  
470 ally less frequent than lower-wind conditions (Shu and Jesson, 2021), further mitigating the impact of these issues. A similar comment can be made with respect to wake detection RMSE increasing with  $I_{amb}$ . Wake steering control brings largest benefits when the wind is less turbulent, which is where the framework shows best performance.

The presented results also highlight that wake detection accuracy is highly dependent on the training data selection. That indicates that improved performance across a broader range of conditions could be achieved by extension of the training  
475 dataset, e.g. by learning the wake deficit shape from various 'receiver' turbines. One of the testing subsets has  $I_{amb}$  equal to

9%, a value outside the training range of 3–7%. While having one of the highest errors in the study, the wakes within the subset are nonetheless detected at correct wind directions. This highlights the framework’s ability to produce reasonable results for wind fields with ambient conditions ‘unknown’ to the estimator. This is highly advantageous for the field application context, where the pre-deployment training procedure would only capture some of the wind effects experienced by the wind farm.

#### 480 4.4 Current limitations

The present methodology treats each YZ wind snapshot entirely independently, it therefore seems clear that improved performance (and solution to some of the problematic cases which are identified) could be readily achieved by extending the methodology to undertake a post-processing analysis which account for time variations in results. This could, for example, allow for the imputation of gaps that occur in characterised time series for more turbulent wakes (see Fig. 14); moreover, by  
485 considering classifications of time-adjacent snapshots, it could help in correct detection of those fully impinged cases which are misidentified as unimpinged. Kalman filtering would seem to be a technique well-suited to these possible methodological extensions.

It should also be highlighted that the application of a moving average filtering within the methodology results in predictions lagging behind the true wind field. This lag ranges from approximately 12 seconds for  $U_{\text{amb}} = 15$  m/s, to approximately 58  
490 seconds for  $U_{\text{amb}} = 5$  m/s. These values are a consequence of matching the filtering window width to the wind field’s typical meandering time scales (see Eq. (7) and (8)). In the context of wind farm flow control, these levels of lag aren’t necessarily problematic, and the lag may be removable by introducing methods such as Kalman filtering. Relevant literature (Luo et al., 2024; Zhou et al., 2023) shows that Long Short-Term Memory (LSTM) networks could potentially provide a short-term forecast of the wake dynamics, thus providing an alternative solution. Further research needs to be conducted to investigate these leads.

Note also that the range of ambient turbulence intensities used for framework testing falls between 3% and 9%, and the atmospheric conditions for both training and testing are considered as neutral. Large offshore wind farms could experience higher levels of turbulence deep within the turbine grid due to multiple wake interactions (Shaw et al., 2022). These simplifications should be acknowledged and other turbulence levels, along with incorporating both stable and unstable boundary layer conditions, analysed in future work. Similarly, turbine yaw offsets are also not considered in the this work. The current analysis  
500 implemented a medium-fidelity wake model, and so further work should also extend this framework to more realistic wake structures, for example those obtained through Large Eddy Simulations.

## 5 Conclusions

The proposed method for generalised wake impingement detection and characterisation shows good performance for a wide range of tested wind conditions. The framework’s effectiveness is sensitive to ambient wind speed and turbulence intensity  
505 levels, with best performance observed for wind speeds between 7 and 13 m/s and turbulence intensities ranging from 3% to 7%. Wind field reconstruction reports high accuracy with an all-around RMSE of 3.7% when normalised by mean ambient wind speed. Wake detection correctly responds to a wake presence, and identifying a correct ratio of impingement throughout

the simulation duration has an average RMSE of 0.23. Wake characterisation appropriately adapts to the meandering motion, achieving high accuracy; wake centre estimation reports average RMSE of  $0.08D$  and  $0.03D$  for  $I_{amb}$  of 9% and 3%, respectively; wake lateral border estimation reports average RMSE of  $0.1D$  and  $0.05D$  for  $I_{amb}$  of 9% and 3%, respectively. This work provides a baseline concept for generalised wake impingement estimation, which, with further improvements, could greatly contribute to better-informed wind farm flow control. Current limitations are identified, with the most important including: shortcomings of the evaluation methods and anomalies in wind sensing. Next steps for the further development of this framework include: validation of the current setup in progressively more realistic environments (including yaw misalignment, higher fidelity wind fields and wakes, or utilisation of field data); an extension of the training dataset (towards accounting more flow phenomena from more turbines at different distances); methodological extension to capture time-variance between individual two-dimensional snapshots and opportunities for imputation and forecasting of wake properties. Kalman filtering is identified as a likely route to extending the framework in this manner.

## Appendix A: Convolutional neural network

The CNNs are a specialized type of deep learning method, optimised for working with grid-like data (most commonly two-dimensional images). Their design is perfectly suited for learning spatial features from input data, making them especially effective for image recognition and classification tasks. Due to several key achievements in recent years, they have revolutionised areas such as face recognition, hand writing analysis or autonomous vehicles (Li et al., 2022). In the context of wind energy, some examples of CNN implementation include wind power prediction (Zhu et al., 2017; Harbola and Coors, 2019), early fault detection and classification (Rahimilarki et al., 2022) and others. The input layer of the CNN is the size of the grid-like data it is processing - in a simple example of a grey-scale image, it would be its width multiplied by height. If the task at hand is to classify the image, for example decide on what handwritten digit does the image show, then the output layer would consist of 10 nodes (one for each digit), each one holding the confidence value between 0 and 1. The actual performance happens in the hidden layers located between the input and output layers, and for most CNNs, that is a combination of following:

- *Convolutional Layer*: applies learnable filters (also called kernels) that slide across the input data, only working on a small patch of the data at a time. A dot product of kernel and data at each position creates a measure of how close a patch of data resembles a given spatial feature such as edge or arch. Doing that for the entire input results in a feature map. Performing that operation through multiple iterations with many kernels, progressively optimizing their weights, allows to combine small features into larger ones and ultimately is the key to detecting patterns.
- *Activation Function*: normally following the convolution layers, various activation functions like ReLU (Rectified Linear Unit) introduce non-linearity, enabling the network to learn complex patterns. It is achieved by restricting the connections between the neurons when the weighted sum is too low.

- 540
- *Pooling Layers*: reduces the spatial size of feature maps, decreasing computational complexity and helping to prevent overfitting. Max pooling is the most commonly used method of doing so, selecting the maximum value from each patch of the feature map.
  - *Fully Connected Layer*: after several cycles of convolution-activation-pooling, this layer connects every neuron in one layer to every neuron in the next, combining features learned by previous layers to produce final predictions.

545 While designing the neural network, one needs to decide on the number and type of hidden layers implemented in its architecture, as well as on the hyperparameters such as number and size of learnable filters. Moreover, as with all deep learning techniques, the performance of the CNN is heavily dependent on the quality of data used for its training.
