Abstract. Reliable wind energy assessment is often limited by reliance on single-point wind measurements at nacelle height, as commonly used in international standards. Here, we present a closed-form analytical rotor-averaging model for turbine power that integrates the vertical variation of horizontal wind speed — the changes in wind with height — using a Taylor expansion of the inflow velocity over the rotor disk. We assess idealised wind profiles to understand the isolated effects of typical shear, veer profiles, and turbulence on the power production of the turbine. This analytical model is then validated against power measurements from five Enercon E92 turbines on the Gotthard Pass, a complex-terrain wind park in the Swiss Alps, across 10 distinct wind events. The analytical model consistently outperforms both OpenFAST simulations and the International Electrotechnical Commission (IEC) standards, providing smoother and more accurate power estimates, reducing RMSE by 8.8% and bias by 25.4% relative to IEC-standard single-point extrapolations. This equates to an annual energy production estimate that is 23.7 *MWh* closer to reality, for a 2.35 *MW* turbine at this specific site. Additionally, it enables effective filtering of wake-affected LiDAR measurements, demonstrating flexibility, robustness, and applicability for pre-construction assessment and wind park expansion in complex terrain.

1 Introduction

Accurately modelling wind turbine power generation requires more than a simplistic application of the power curve at hub height. Traditional wind turbine power curves, as formalised in the IEC 61400-12-1 standard, rely on average wind speed measurements at hub height, an approach that fails to capture complex meteorological conditions that can significantly affect actual power production (IEC, 2022; Santos et al., 2015). The uncertainty of power performance measurements is closely linked to wind velocity variations, turbulence, and other atmospheric boundary layer processes, effects that remain insufficiently understood despite the increasing size of modern wind turbines (Belu and Koracin, 2012).

Although multi-height wind measurements from meteorological masts and Doppler wind LiDAR are widely used and addressed in international standards, power performance evaluation typically reduces the vertically varying inflow across the

rotor-swept area to a single representative wind speed. This quantity is commonly obtained from a nacelle-mounted anemometer, calibrated against the incoming kinetic energy flux measured across the blade-swept area approximately 2.5 rotor diameters upwind of the turbine at the test site. While this approach is appropriate for standardised test locations characterised by flat or mildly complex terrain, it implicitly assumes quasi-uniform inflow conditions across the rotor disk. In complex terrain, strong vertical and lateral wind velocity gradients arise from wind shear, directional veer, turbulence, yaw misalignment, and wake effects, rendering this calibration insufficient to represent the true rotor-integrated inflow and leading to increased uncertainty in power curve application.

Turbulence intensity plays a particularly important role in shaping measured power curves, as standard 10-minute averaging procedures obscure short-term wind variability and complicate comparisons with guaranteed power curves (Albers, 2010). Wind shear and directional veer further modify the effective inflow experienced by the turbine, such that alignment with hub-height winds may result in suboptimal or superoptimal power production depending on the vertical wind profile (Murphy et al., 2020). These effects are amplified in complex terrain, where the upstream flow field is inherently non-homogeneous, leading to altered wake development and induction behaviour compared to turbines operating in flat, homogeneous environments (Troldborg et al., 2022). Despite these known limitations, the reduction of spatially varying inflow to a single-point wind speed representation remains the prevailing standard for historical consistency in turbine power assessment (IEC, 2022).

In recent years, simulations and analytical approaches that explicitly account for spatial wind velocity distributions have gained attention for their ability to capture key physical processes influencing turbine power output. Modified power curve and induction models incorporating wind shear, veer, turbulence intensity, and yaw misalignment have been shown to improve power prediction accuracy by up to 51% (Vahidzadeh and Markfort, 2019, 2020). Similarly, coupling actuator disk theory with blade-element models to resolve vertical shear and directional wind changes improves correlation with observed turbine power and reduces prediction errors (Mata et al., 2024). In the context of wind-farm-scale interactions, Gaussian process and random forest approaches further demonstrate the importance of accounting for wake-induced turbulence and vertical wind profile variability, showing good agreement with large-eddy simulations and field observations (Niayifar and Porté-Agel, 2015; Clifton and Wagner, 2014).

Field measurements confirm that such intra-rotor flow variability can lead to substantial deviations from standard power curves. Discrete combinations of wind speed shear and directional veer have been shown to induce power production changes ranging from -19% to +34% relative to the nominal power curve for a given hub-height wind speed (Mata et al., 2024). Differences between hub-height wind speed and rotor-equivalent wind speed (REWS) can result in power deviations exceeding 70 kW, corresponding to up to 5% of rated power for a single utility-scale turbine (Murphy et al., 2020). These discrepancies scale to wind-farm level and can lead to significant instantaneous and cumulative power prediction errors.

Advanced measurement techniques using ground-based Doppler wind LiDAR enable the retrieval of wind speed and direction profiles across the entire rotor-swept area, allowing equivalent wind speeds to be derived based on kinetic energy flux rather than single-point measurements (Wagner et al., 2011). While the IEC 61400-12-1 standard acknowledges that non-uniform inflow conditions, particularly vertical and horizontal shear and turbulence within the rotor-swept area, can significantly bias power performance measurements, it stops short of prescribing analytical methods to account for these effects, instead sug-

gesting the use of weighted average wind speeds (IEC, 2022). This leaves a clear gap for physics-based formulations capable of explicitly resolving spatial wind variability across the rotor plane.

In this study, we address this gap by proposing an analytical formulation for wind turbine power generation that does not treat wind speed as a single scalar input but instead evaluates the turbine power equation as an integral over the rotor-swept area, incorporating the vertically varying wind velocity profile. We refer to the combined influence of wind shear, directional veer, turbulence intensity, and yaw misalignment across the rotor disk as the intra-rotor flow structure, which governs the true kinetic energy flux intercepted by the turbine.

To assess the performance of our analytical integration approach, we rely on numerical simulations from OpenFAST, an open-source wind turbine simulation tool developed by NREL (Jonkman, 2013). OpenFAST resolves turbine dynamics under realistic, spatially and temporally varying wind inflow, effectively capturing the intrarotor flow structure we aim to represent analytically.

This study focusses specifically on a highly complex wind park site located at the Gotthard pass, in the heart of the Swiss Alps at 2106 m a.m.s.l. We make use of SCADA data from the five Enercon E92 (2.35 MW) wind turbines installed there, while modelling a virtual wind turbine with open-source blade geometry, that is similar to the Enercon E92. High-resolution wind profiles are taken from the Gotthard Transect Experiment (van Schaik et al., 2025b), which includes LiDAR profiles collected at 10 sites along a transect crossing through the Gotthard Wind Park. These LiDAR measurements not only provide wind speed and direction at 10 m vertical resolution, but also Turbulence Intensity (TI), which can be compared with real-world turbine performance under several complex flow conditions measured throughout the 3-month summer campaign.

In this manuscript, we present and evaluate an analytical formulation for wind turbine power generation based on integrating wind velocity variations over the rotor plane, with a focus on vertical shear and turbulence effects. Benchmarked by model results of the same wind profiles in OpenFAST, we explore the various sources of error that are eliminated by, or still present in this novel method and present the improved accuracy of predicting wind turbine power from standard wind profile measurements.

2 Methodology

Consider the standard wind turbine power equation, derived from the rotor disc model in equation 1:

$$P(v, z) = \frac{1}{2} C_p(v) \rho A v(z)^3 \quad (1)$$

where $P(v, z) [kW]$ is the power extracted by the turbine at wind speed $v(z) [m s^{-1}]$, $C_p(v) [-]$ is the power coefficient, representing the efficiency of the turbine at converting kinetic energy into mechanical energy, $\rho [kg m^{-3}]$ is the air density which is assumed to be constant throughout the swept area of the blade, $A = \pi R^2 [m^2]$ is the rotor-swept area with R the rotor radius, and $v(z)^3$ reflects the cubic dependence of power on wind speed. In this formulation, wind speed is typically assumed to be uniform and measured at hub height.

However, in reality wind velocity varies vertically and horizontally due to atmospheric shear. Among these, vertical variations across the rotor-swept area are usually the dominant factor, often far exceeding horizontal deviations. This dominance

90 of vertical variations is well established in boundary-layer meteorology (Stull, 1988) and wind energy practice (Wagner et al., 2014; IEC, 2022), where horizontal variations across the rotor disk are usually minor compared to the strong vertical gradient in wind speed.

2.1 Analytical method

To address these vertical variations in the horizontal wind speed, we integrate over the rotor-swept area as shown in Figure 1.

Figure 1. Vertical integration over the rotor-swept area of a wind turbine.

95 From which we find equation 2:

$$P(v) = \frac{1}{2} C_p(v) \rho \int_{-R}^R 2\sqrt{R^2 - z^2} v(z)^3 dz \quad (2)$$

Where $R[m]$ is the radius of the rotor-swept area of the turbine, and $z[m]$ is the vertical variable. Here, one can integrate over any vertical wind speed function; however due to the cubic relation with wind power, this integral often has no analytical solutions.

100 Since the vertical wind profile is continuous and differentiable across the whole rotor-swept area, one can expand the wind profile into its Taylor series:

$$v(z) = \sum_{i=0}^N c_i z^i = c_0 + c_1 z + c_2 z^2 + \dots + c_N z^N \quad (3)$$

By inserting the series expansion of Equation 3 into the integrand of Equation 2, the integral can be solved analytically for any wind profile $v(z)$. The full derivation is given in A, with the resulting expression shown in Equation 4:

$$105 \quad P(v) = \frac{1}{2} C_p(v) \rho A \sum_{i,j,k=0}^N c_i c_j c_k R^m \frac{m!}{2^m (\frac{m}{2}!)^2 (\frac{m}{2} + 1)}, \quad m = i + j + k \mid m \text{ is even} \quad (4)$$

Where the summation refers to a triple summation over all Taylor expansion coefficients i, j & k . This is particularly useful to assign an approximate, but continuous function to the discrete wind profile measurements, such that the following derivation

can be treated analytically. The fractional term with m is the reciprocal factor resulting from an integration of a variable raised to an exponent shown in Table 1. Crucially, this factor is set to 0 for uneven values of m . The summation is terminated by N , which can be increased arbitrarily to converge the Taylor series as close to the original function $v(z)$ as desired, but will result in several higher-order terms, which exponentially decrease in contribution to the power production of the wind turbine.

Table 1. Lookup table of the fractional term in equation 4.

m	fraction
0	1
2	$\frac{1}{4}$
4	$\frac{1}{8}$
6	$\frac{5}{64}$
8	$\frac{7}{128}$
10	$\frac{21}{512}$

To facilitate the use and reproducibility of the method presented here, we provide an open-source workflow that automates the two steps of solving for equation 3 & 4: a) given arrays of measured wind speeds v and heights z , the code fits a Taylor polynomial of user-selected order N (recommended at $N = 3$), and b) evaluates equation 4 exactly by performing the triple
 115 summation, applying the fraction terms in Table 1, and returning the total power $P(v)$ together with per-order contributions of m . The code accepts R , ρ , and a tabulated $C_p(v)$ curve that sufficiently covers the working wind speed range of any wind turbine. The $C_p(v)$ tabulated data is selected by the spatial average of the wind speed across the swept area of the blade, as to represent the coefficient of performance most accurately to any arbitrary wind profile. The archived, citable release containing these scripts and an example of the Enercon E92 wind turbines, used in this study, are available on Zenodo (van Schaik et al.,
 120 2025a). We refer the reader to the Data Availability section of this manuscript for more details.

2.1.1 Turbulence

For the case of turbulence, we must briefly depart from the formulations above and instead focus only on the second-order statistics of wind speed fluctuations. While measurements from van Schaik et al. (2025) show that a Student-t distribution provides the most accurate fit, we assume a normal distribution with mean \bar{v} and standard deviation σ_v , as it is the only second-
 125 order distribution that allows for analytical treatment. It has been shown that a linear scaling factor of 1.81 applied to σ_v effectively accounts for the heavier tails of the Student-t distribution in the case of the Gotthard Transect Experiment for all wind directions and speeds. Therefore, the estimated probability density function describing the turbulence is assumed to be:

$$f(v) = \frac{1}{\sqrt{2\pi}\sigma_v} \exp\left(-\frac{(v - \bar{v})^2}{2\sigma_v^2}\right) \quad (5)$$

To realistically estimate the impact of turbulence on power production, the expected power output in the presence of tur-
 130 bulence must be obtained by integrating the full turbine power curve $P(v)$ (eq. 1) over the probability distribution of wind speeds:

$$\Delta P_{\text{turb}}(\bar{v}, \sigma_v) = \int_{v_{\text{in}}}^{v_{\text{out}}} P(v) f(v) dv \quad (6)$$

Where $\Delta P_{\text{turb}}(\bar{v}, \sigma_v) [kW]$ gives us the contribution of turbulence which is positive in the convex part of the power curve, and negative in the concave part of the power curve. To assess its validity, we compared the turbulence contribution against theoretical wind profiles with constant height in OpenFAST, showing good agreement with the analytical solution (Fig. 6b, further detailed in the Results).

Previous studies have demonstrated that OpenFAST is a highly accurate tool for generating realistic turbulent wind fields, particularly through the stochastic modelling capabilities of TurbSim. In particular, the work of Brown et al. (2024) validated the performance of OpenFAST by comparing turbulent simulations against 253 ten-minute bins of turbine measurement data collected during normal operation. Their results showed strong agreement in both power performance and structural load predictions. Beyond its validated accuracy, OpenFAST has also been widely adopted as a reference framework for advanced wind energy modelling and simulation in turbulent conditions. As described by Sprague et al. (2020), OpenFAST constitutes the core aeroelastic solver within their ExaWind multifidelity modeling framework, enabling coupling with turbulence-resolving flow solvers such as large-eddy simulations as well as lower-fidelity inflow models. This modular and physics-based architecture makes OpenFAST particularly well suited as a baseline for the validation of our analytical model in the context of turbulent flows in complex terrain.

Here, we propose to use the following analytical approximation of the turbine power curve $P(v)$, which fits both the Enercon E92 and many other commercial wind turbines well (van Schaik et al., 2025c, d):

$$P(v) \approx P_r \left(1 - \exp \left[- \left(\frac{v - v_{\text{in}}}{B} \right)^C \right] \right) \quad (7)$$

This formulation captures the rapid increase in power after cut-in, and the saturation near rated power. Parameters B and C can be adjusted to fit the performance of a specific turbine.

Having established a general framework for turbulence inclusion in an analytical fashion, we can now return to equation 6 and extend it to account for vertical wind speed gradients across the rotor-swept area – which represents turbulence – by calculating the correction term. This method and code is also archived on Zenodo as a citable release of scripts along with example data of the Enercon E92 turbines including wind and turbulence profiles from the Doppler wind LiDAR of the Gotthard Transect Experiment (van Schaik et al., 2025a).

2.1.2 Wake filtering

Another useful feature of the Taylor-expanded wind profile is that it naturally enables the removal of anomalous or clearly unphysical measurements before constructing the analytical profile. Because our method relies only on a small number of vertically adjacent points, any range gates that contain erroneous values, such as flow disturbances caused by upstream turbine

wakes, can simply be discarded with few consequences for the overall reconstruction of the wind profile. This approach is appropriate either when the objective is to recover the undisturbed wind profile, or when the LiDAR happens to sit inside a wake while the turbine location of interest lies just outside of it. The Taylor expansion is then fitted to the remaining clean measurements immediately above and below the wake region, yielding an interpolated representation of the approximated
165 undisturbed wind field.

The same filtering approach extends directly to the turbulence statistics. Wakes typically manifest as abrupt increases in the standard deviation of the horizontal wind, σ_v . These range gates can be removed in the same manner as for the mean wind speed to create a wake-free estimate of the turbulence structure. These Taylor expansion parameters of the mean wind and turbulence profile then serve as the input to Equation 4 as discussed above.

170 2.2 Numerical method

To validate the developed equations, we make use of OpenFAST coupled with TurbSim to simulate any inflow wind profile applied to a single wind turbine. OpenFAST is a multi-physics simulation tool developed by the National Renewable Energy Laboratory (NREL) in the United States (Jonkman, 2013). In this study, the following OpenFAST modules were activated: InflowWind, ElastoDyn, AeroDyn, and ServoDyn. All settings were kept at their default values, with two exceptions.

175 Firstly, the shaft tilt angle was set to 0° (instead of the default 5°) in order to remain consistent with the analytical method, which assumes a purely horizontal inflow and maximises power capture under that condition. Although the Enercon E92 turbine is built with a shaft tilt, this simplification is acceptable because our final comparison is between the analytical model and the OpenFAST model, for which the associated errors largely cancel out. When comparing to the measured power output of the turbine (P_{true}), setting the shaft tilt to zero introduces a small bias of approximately $8 kW$ for the $2.35 MW$ turbine. However,
180 since the wind profile is based on a LiDAR measurement located roughly $100m$ from the turbine, any slight decrease in horizontal inflow or the inclusion of vertical wind components caused by shaft tilt would not significantly improve the accuracy. Therefore, we chose to retain the simpler configuration which are comparable to the idealised wind profiles.

Secondly, the degrees of freedom associated with tower deformation were disabled to focus the analysis on wind effects and power production, excluding the influence of structural flexibility.

185 TurbSim is a stochastic turbulence simulator primarily designed for use within the InflowWind module. In this study, TurbSim is not only used to generate turbulent wind fields but also to input user-defined wind profiles via the WindProfileType option. These files are then read by the InflowWind module to provide the wind data necessary for the OpenFAST simulation, thus enabling realistic wind input with vertical variations.

To ensure a reproducible approach, the wind turbine model selected is part of a reference series developed by the NREL to
190 serve as standard benchmarks. This series is known as WindPACT, and we use the $3.0 MW$ NREL WindPACT turbine for our numerical studies, as it is the closest open-source representation of the Enercon E92 turbines deployed on the Gotthard pass. The exact specifications of both turbines can be found in Table 2. While the NREL $3.0 MW$ WindPACT turbine differs from the Enercon E92 $2.35 MW$ in terms of rated power, rotor diameter, and specific blade geometry, it represents the closest openly available model for numerical simulations in OpenFAST. We cannot directly use the Enercon E92 as its blade geometries and

- 195 aerodynamic specifications are proprietary. Any discrepancies in rated power or rotor characteristics between the two turbines must be accounted for in the following methodology.

Table 2. Specifications of the Enercon E92 and NREL WindPACT turbines.

Turbine	Enercon E92	NREL WindPACT
Location	Gotthard pass	OpenFAST
Blade diameter	92 m	100 m
Nacelle height	98 m	119 m
Rated power	2.35 MW	3.0 MW
Rated wind speed	14 m s ⁻¹	12 m s ⁻¹
Cut-in wind speed	2 m s ⁻¹	1 m s ⁻¹
Cut-out wind speed	25 m s ⁻¹	NONE
Air density	0.996 kg m ⁻³	0.996 kg m ⁻³

Each simulation runs for 12 minutes of turbine operation under steady wind conditions, meaning that both the mean wind speed and the turbulence intensity are held constant throughout the simulated period. During the first 2 minutes, the turbine adjusts from its initial power setting of 3.0 MW to the stable operation power. To avoid including this adjustment period, the average power output is calculated over the final 10 minutes. Power curves are generated for wind speeds ranging from 1 m s⁻¹ to 25 m s⁻¹ in increments of 1 m s⁻¹, resulting in 25 simulations per power curve.

2.3 Idealised wind profiles

To compare the influence of specific parameters, the difference in power output $\Delta P_{\text{parameter}} [kW]$ between the reference and the modified configurations is evaluated using the following expression:

$$\Delta P_{\text{parameter}} = P_{\text{parameter}} - P_{\text{ref}} \quad (8)$$

where $P_{\text{parameter}} [kW]$ is the power output with the parameter under study, and $P_{\text{ref}} [kW]$ is the power output from the reference case. The reference case corresponds to an horizontal, constant and uniform wind profile with no turbulence, which is detailed in section 3.2.

We preface the more complex simulations from the Gotthard Transect Experiment with several idealised profiles to understand the effects of individual wind profile phenomena. In this study, we will cover the following idealised wind profiles:

[a)]

1. Uniform profile (reference case): is the most simplistic case where $\frac{dv}{dz} = 0$, i.e. the wind speed is not a function of height. This is used as the reference case for comparing to the standard power curve model in the IEC standard, defined by equation 1. In our study, we likewise adopt this uniform profile as the base case, against which the subsequent idealised wind profile scenarios are compared.

2. Linear shear: $v(z) = az + \bar{v}$ (Fig.2a). Where, the analytical power production can be derived by equation 9:

$$\Delta P_{\text{shear, an}} = \frac{3}{4} \cdot \frac{R^2 a^2}{\bar{v}^2} \cdot P_{\text{ref}} \quad (9)$$

Where the subscript *an* refers to the analytical solution derived from the integral Eq. 2, $a = 0.01/0.025/0.05 [s^{-1}]$ is the shear coefficient, and $z = 0m$ at the nacelle of the turbine, and $-R$ and R and the bottom and top of the swept area of the blade. Figure 2a illustrates the shear parameter across the rotor area.

3. Linear veer: where $\frac{d\theta}{dz} = \alpha = \text{const.}$, such that the wind profile is defined as $v(z) = \bar{v} \cos(\alpha z)$ (Fig.2c). Such that, the analytical power production is given by equation 10:

$$\Delta P_{\text{veer, an}} = -\frac{3}{8} \cdot \alpha_{\text{max}}^2 \cdot P_{\text{ref}} \quad (10)$$

where $\alpha_{\text{max}} = \alpha R = 5/10/22.5 [^\circ]$ is the maximum angular deviation at the upper and lower extents of the rotor-swept area. Figure 2c shows the definition of this veer parameter.

4. Vertically-constant TI: in which the Turbulence intensity is defined as $TI = \frac{\sigma_v}{\bar{v}}$, and it is constant with height $\frac{dT I}{dz} = 0$. Here, the analytical power production can not be expressed analytically in closed form, but is best represented in integral form (eq. 6). In which, the turbulence intensity is governed in TurbSim by the parameter "IECturbc", where the user can simply enter $TI = 10/15/20/25\%$.

5. Logarithmic wind profile: is a typical wind profile used in a plethora of boundary-layer studies, defined by a logarithmic relation between wind speed and height: $v(z) = \frac{u^*}{\kappa} \ln\left(\frac{z}{z_0}\right)$ (Fig.2b). Where $u^* [m s^{-1}]$ is the friction velocity, $\kappa \approx 0.41$, is the Von Kármán constant, and $z_0 = 0.1 [m]$ is the surface roughness. It is the most realistic theoretical wind profile of wind over a surface. From this, the power curve can be calculated by equation 4, with no closed-form solution.

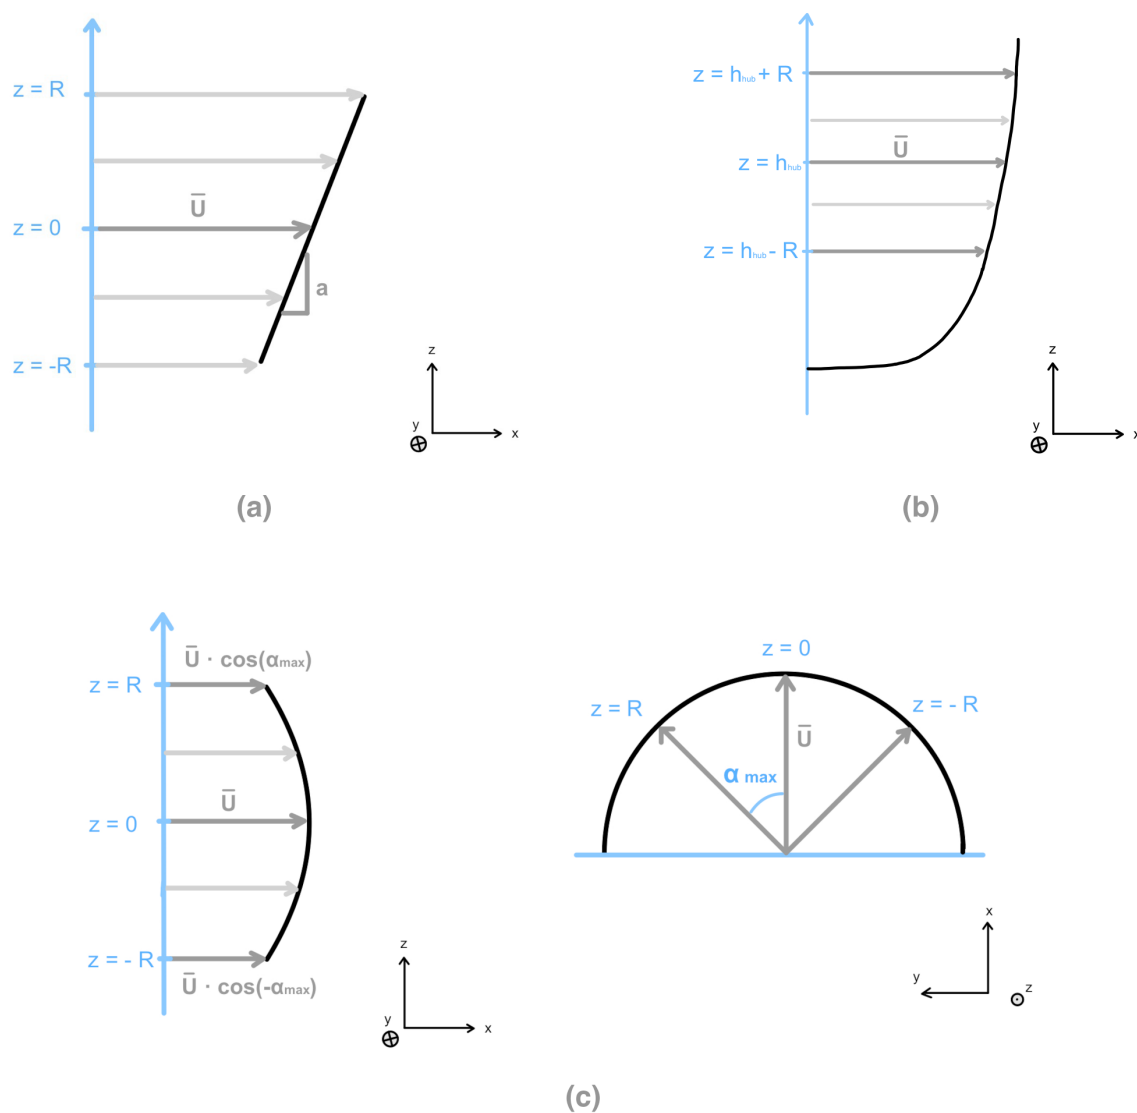

Figure 2. Idealised vertical wind profiles used in controlled simulations: (a) linear shear, (b) Logarithmic wind profile, and (c) linear veer.

2.4 Measured wind profiles

235 Wind power output and nacelle wind speed data at 10-minute resolution were extracted from van Schaik et al. (2025b) for each of the five Enercon E92 wind turbines located at the Gotthard Wind Park. This wind farm is situated 2106 m above mean sea level (a.m.s.l.), north–south-oriented Gotthard Pass in the central Swiss Alps. The surrounding terrain is highly complex and characterised by strong topographic channelling of the prevailing northerly and southerly winds. Linear shear and veer are consistently observed across all turbine sites, caused by upwind obstacles such as indicated orange in Figure 3a, and are known
240 to impact rotor performance. Notably, the individual output of two turbines on the pass is approximately half that of each of the other three turbines, a disparity that cannot be explained by differences in mean wind speed alone.

In 2023, the site hosted a Doppler wind LiDAR campaign in which the instrument was deployed at 10 locations near the turbines over a three-month period (Figure 3). This resulted in detailed wind profile measurements capturing both prevailing wind directions at each turbine site. The LiDAR retrieved three-dimensional wind velocity vectors at 10 m vertical resolution
245 between 40 m and 160 m above the instrument, and at 20 m resolution from 160 m to 300 m. Given the Enercon E92 nacelle height of 98 m and rotor diameter of 92 m, this setup provided 6 to 9 discrete wind speed and turbulence intensity measurements at 10 m increments within the rotor-swept area, depending on the LiDAR location.

Figure 3. Turbine and LiDAR locations from the Gotthard Doppler wind LiDAR campaign in the Summer of 2023, from van Schaik et al. (2025b) Fig. 2 and 3.

2.5 Gotthard wind data: Analytical and simulation workflow

The Doppler wind LiDAR profiles were also used to investigate the impact of vertical variations in incident wind speed ($v(z)$), and turbulence ($\sigma_v(z)$) measured by the LiDAR) in the rotor-swept area. Each measured wind profile is interpolated using a polynomial approximation (Eq. 3), of the order $N = 3$, and inserted into our analytical framework (Sec. 2.1), to compute expected turbine power output.

To compare these results to the state-of-the-art, the same LiDAR profiles are used as input for OpenFAST simulations whose results are then compared to the actual power production of the five Enercon E92 turbines. For each of them, a near-by and upwind LiDAR deployment location is selected based on the two prevailing wind directions: Northerly and southerly. For each of the ten cases, we define a four-hour time window (subject to data availability) from which the corresponding LiDAR profiles are extracted for the simulations. Since the OpenFAST simulations are run on the NREL's reference WindPACT 3.0 MW turbine whose dimensions differ from the Enercon E92, a rescaling of the LiDAR profiles is performed. This transformation is a simple linear mapping, which scales the profiles to account for the height difference between the turbines, and includes any variation of altitude between the base of the Enercon E92 and its respective LiDAR deployment location. The heights of the LiDAR profiles are rescaled with Equation 11:

$$z_{new} = \frac{50}{46}(z_{old} + \Delta z_{lidar}) + 12.478 \quad (11)$$

where $z_{new}[m]$ is the rescaled height point, $z_{old}[m]$ the original height point, $\Delta z_{lidar}[m]$ the altitude difference between the lidar and the turbine's base. The first factor results from the blade length of the WindPACT 3.0 MW ($R_{WP3.0} = 50m$) versus the Enercon E92's ($R_{E92} = 46m$). The additional constant $12.478m$ is simply a fit constant.

This scaling only affects the height values in the profiles; all the other variables are directly derived from the raw data of the LiDAR, which includes the velocity $v(z)$ and the wind speed dispersion $\sigma_v(z)$. Each transformed profile is then used as input for the TurbSim module prior to running the OpenFAST simulation. Regarding turbulence, two cases are considered when setting up TurbSim: Firstly, for simulations discarding turbulence, the turbulence model of TurbSim is set to *IECKAI* and the *IECturb* parameter is set to 0 inside the `TurbSim.inp` file. This setup enables the definition of a custom wind profile inside the `TurbSim_User.profiles` while ensuring that the turbulence intensity is set to 0%.

Secondly, for simulations including turbulence, the Turbulence Model is set to *USRVKM*. This model discards the *IECturb* parameter and enables user-defined *standard deviation* and *length scale* profiles to be defined in the `TurbSim_User.profiles` in addition to the velocity profile.

The standard deviation $\sigma_v(z)[m/s]$ values are derived directly from the wind speed variability measured by the LiDAR. The length scale profile defines the size of the energy-containing eddies that cross the swept area with respect to the height. They are used by TurbSim to compute whether the eddies have a constructive or destructive effect on the transfer of wind power over the swept area. Since length scales were not part of the LiDAR measurements, the profile is set to the standard values of TurbSim as $l = [3, 4, 6, 9, 13, 13, 13, \dots][m]$.

The *USRVKM* model also takes into account standard eddies scales along the (u, v, w) axes – u oriented along the wind flow, v vertical. These scales define the aspect ratio of the eddies globally; if all scales are identical, the eddies are considered spherical by TurbSim. Again, since this parameter is not part of the LiDAR measurements, the scales are set to default for the simulations, that is, $(1.092, 1.0, 0.534)$.

The TurbSim module then computes a binary file `TurbSim.bts` which is called by the OpenFAST input file `InflowWind.dat` when starting the simulation. Similarly to 2.2, the simulation is then run over 12min, and only the last 10min are considered in the final power output. Before comparing to the real power production of the Gotthard turbines, this output is scaled down by a factor $k = \frac{2.35MW}{3.0MW}$ to account for the difference of rated power of the WindPACT turbine (3.0 MW) used in the simulation and of the Enercon E92 (2.35 MW) installed at the Gotthard.

In summary, the complete workflow of measured data variables, and how they are used in the analytical and OpenFAST simulations, is outlined in the schematic in Figure 4.

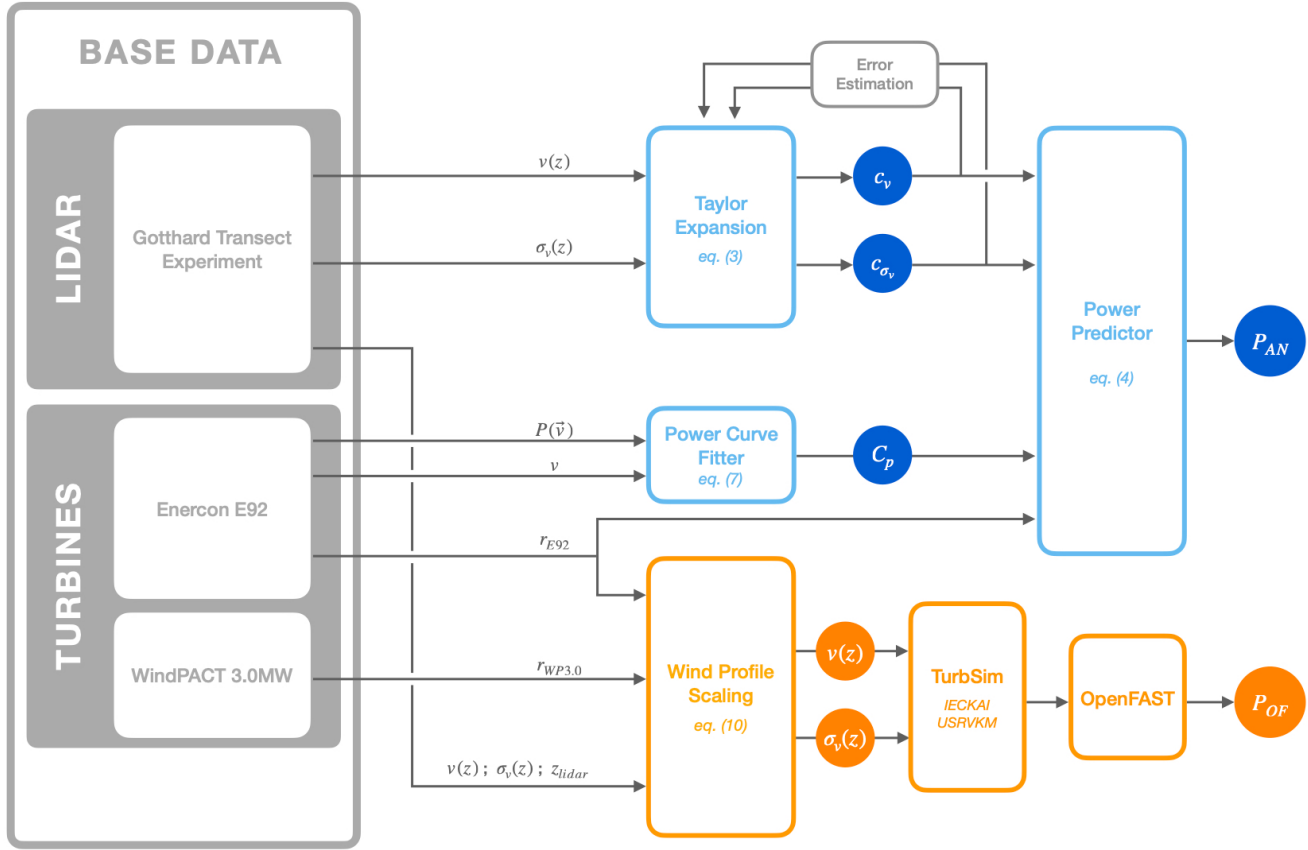

Figure 4. Schematic of the Analytical and OpenFAST model workflow.

2.5.1 Model evaluation

To evaluate the performance of the analytical model versus the OpenFAST simulations, we compare their predicted power output against the measured production of the five Enercon E92 turbines at the Gotthard Wind Park. Each turbine is assessed separately for the two prevailing wind direction (northerly and southerly), resulting in ten validations cases. For every case, we have selected a four hour window of 10-minute data, which provides one LiDAR-derived wind profile from the nearest LiDAR location to the turbine, and one corresponding turbine power measurement per time step.

For each of the ten cases, we compute the bias between the modelled and observed power over the 4 hour window. This results in a four bias estimates per case: analytical with and without turbulence, and OpenFAST with and without turbulence. A single southerly case is excluded from this analysis due to the presence of a turbine wake, which is discussed separately in the results.

In addition to the per-case biases, we assess overall model skill by combining all (wake-free) cases and compute RMSE, MAE and R-squared for each of the four model configurations. This pooled evaluation provides an overarching summary of model performance in varying atmospheric conditions and turbine responses in highly complex terrain.

Finally, we quantify model improvement using the relative reduction in bias between OpenFAST and the Analytical model as this is the key metric to model performance for each individual case. The global skill metrics are compared relatively between both models as well as the true measured power of the wind turbine. The inclusion of turbulence in the models is evaluated separately to assess the importance of this additional variable.

This contrasts with the method used for the idealised wind profiles, where we compare each profile to a uniform reference wind field to compute the power differences (ΔP) and isolate the contribution of each effect.

3 Results and Discussion

The following results assess the performance of the newly derived analytical model against both the IEC standard methods and high-fidelity OpenFAST simulations. Traditionally, the IEC standard approach relies on a single-point wind speed measurement, taken either at nacelle height or scaled from two-thirds of nacelle height, which neglects vertical wind profile variations. Our analytical model aims to overcome this limitation by explicitly accounting for vertical wind structure, while remaining computationally efficient.

We begin by examining the differences in turbine power curves and their curvature, since these strongly influence how vertical variations in wind speed translate into power production. Next, we isolate the effects of typical features of vertical wind profiles, which includes shear, veer, and logarithmic wind profiles, as well as homogeneous turbulence intensity, through idealised wind profile test cases. We then apply the model to ten real-world cases applied to the five turbines at the Gotthard Pass, distinguishing between northerly and southerly flow conditions. Finally, we highlight one case strongly affected by wake interactions, and demonstrate how wake filtering can be applied to recover the undisturbed power signal and improve power prediction significantly.

3.1 Differences in power curves

For the analytical model, we align with the Enercon E92 2.35 MW wind turbines installed at the Gotthard Wind Park. Power curve data is taken from the Enercon E92 specification sheet and is fitted (Equation 7), resulting in a smooth analytical expression (Fig. 5a).

Remaining with Figure 5, the OpenFAST simulations cannot be based on the Enercon E92 directly, as the required blade geometry to simulate power production is proprietary. Instead, the open-source WindPACT 3.0 MW turbine is used. This has consequences in all upcoming results since the turbine behaves differently due to the small variations in the shape of the powercurves. For example, the WindPACT turbine's $C_p(v)$ exhibits unrealistic features starting at extremely high values after which it remains unrealistically constant until the rated power is reached. Furthermore, the turbine power curve lacks defined

cut-in and cut-out wind speeds, causing the model to produce power under wind conditions where a real turbine would not operate. This likely leads to an overestimation of energy production, particularly during very low and very high wind events.

Crucially, there is a difference in how these two power curves were derived; the Enercon E92 power curve results from long-term measurements which average over a large number of real wind profiles. This is strictly different from the WindPACT wind profile which is based on a uniform wind profile where v is constant with height, i.e. the reference case mentioned in 2.3. In reality the uniform wind profile assumption could be better represented by a logarithmic or power-law wind profile that more closely represents the wind profiles incident on the Enercon E92. However, this introduces an additional shear parameter (i.e. z_0 or α) that we can not accurately define as the wind profile information regarding the Enercon E92 power curve calibration was not reported. One could attempt to estimate this value knowing the test site topography, but uncertainties would remain as this shear parameter is largely influenced by atmospheric stability and wind direction (Bot, 2016; Emeis, 2005).

Furthermore, the IEC 61400-12-1:2022 standard outlines that the power curve calibration – as performed for the Enercon E92 – requires the use of a nacelle-mounted LiDAR which performs a cubic-weighted average of the incoming wind field at nacelle height (IEC, 2022; Wagner et al., 2011). Considering that commercially available nacelle-mounted LiDARs tend to scan in a cone pattern, wind speed values from the entire swept area of the blade will be included in this averaging (Letizia et al., 2023; Rettenmeier et al., 2013). According to the standard, the nacelle-mounted anemometer shall be calibrated to this spatially cubic-weighted average windspeed. This would indeed convert the realistic, non-uniform wind profile into a single wind speed value, which can be treated as constant throughout the whole swept area of the wind turbine; in other words, a uniform flow profile.

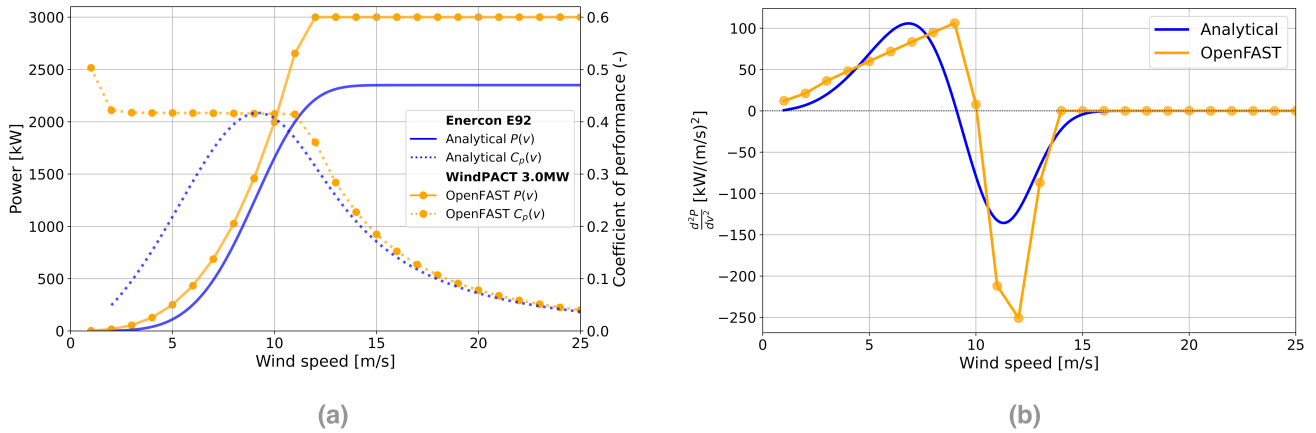

Figure 5. Comparison of the Enercon E92 2.35 MW and WindPACT 3.0 MW powercurve, coefficient of performance and curvature. (a) Powercurves $P(v)$ and coefficients of performance $C_p(v)$, and (b) Curvature of the powercurves.

350 The powercurve's second derivative, representing the curvature, is shown in Figure 5b. This curvature is physically relevant, since it is directly responsible for the power production response on vertical wind speed variations across the swept area of the turbine. When parts of the turbine blade sweeps through different wind speed regimes, this curvature controls the degree to which these variations translate to power production. Notice the smooth curvature of the analytical Enercon E92 power curve, while the WindPACT 3.0 MW turbine exhibits a linear increase before an abrupt drop. The same features of linear power
 355 discrepancies and abrupt changes are observed throughout the following results.

3.2 Idealised wind profiles

The comparison between the power expectation from OpenFAST and the analytical model is summarised in Figure 6. For linear shear (Figure 6a), we find that shear effects contribute positively to the power production of the turbine in comparison to the homogeneous wind profile. The OpenFAST model consistently increases with shear, reflecting the cubic dependence
 360 of power on wind speed ($P \propto v^3$), where higher wind speed contribute more significantly to the overall output. Above the rated wind speed, ΔP tends to 0 as the turbine saturates at its maximum capacity and the extra wind speed is not able to positively contribute to the power production. This is particularly well illustrated by the sudden drop of the OpenFAST curve at $v = 12 \text{ m/s}$. For the analytical model, the rated power is reached more smoothly at $v = 14 \text{ m/s}$ which can directly be attributed to the smoother curvature of the power curve as reported in Section 3.1.

365 Concerning the differences in the two models, we can observe two elements: the apparent overestimation of the analytical model, and the linear behaviour of the OpenFAST curve for low velocities. The overestimation of the power difference in the analytical model is most likely caused to the several reducing factors not taken into account in the analytical model. For

example, the OpenFAST considers the reduced efficiency of energy transfer from the wind to the turbine blade due to non-ideal angle of attack. Additional shearing forces and vibrations, that will inevitably cause additional friction and reduced power production in reality.

In the case of linear veer, shown in Figure 6b, the observations are analogous to the shear, but lead to a reduction in power output instead of an increase. This reduction arises from the diminished effective wind velocity component normal to the rotor plane, which is caused by the veer angle. The shape of both power difference curves are similarly more abrupt for the OpenFAST model due to the less refined and realistic power curve, and the analytical model reports higher differences due to a lack of dampening factors that are present in OpenFAST.

The ΔP curves of homogeneous turbulence, shown in Figure 6b, has a characteristic shape which has previously been reported in similar works such as Gasser et al. (2025). For low wind speeds, up to the inflection point of the power curve, turbulence tends to increase power production. This is because the turbulence velocity distribution, which is symmetric up to second order, places greater weight on velocity realisations above the mean. This holds true for the region in the power curve where the curvature is convex (i.e. positive in Fig. 5b), these higher velocities contribute disproportionately to the average power. Beyond the inflection point, however, the situation is reversed: the turbine response starts to saturate and the contribution of velocities below the mean becomes more significant than that of velocities above it. As a result, the net effect of turbulence is a reduction in power output.

The behaviour at the tail of the curve differs markedly between the two approaches. While the analytical model predicts no change in mean power above rated wind speed, the OpenFAST simulations show a small linear reduction. This behaviour is most plausibly explained by control-system and actuator dynamics under high turbulence: rapid fluctuations in effective angle of attack lead to persistent pitch-tracking errors (due to sensor/estimator lag, pitch-rate and torque limits, and anti-windup), so the controller cannot hold the blades exactly at the optimum. The result is a small shortfall from the rated power setpoint that increases with turbulence intensity. Although our field dataset contains limited observations above rated wind speed, previous studies show that modern pitch-regulated turbines are designed to maintain constant power in this regime through active control adjustments Rosmin et al. (2010); Sedaghat et al. (2016).

The final idealised profile which we will discuss is the logarithmic profile shown in Figure 6c, a common profile that is used to describe the standard wind shear of the earth's surface. The curvature effects previously described for the linear shear still hold in this simulation. A noticeable observation is the relatively low impact of the logarithmic profile, with the maximum deviation from the uniform inflow amounting to only about 15 kW. The logarithmic profile resembles the linear shear profile in shape, however the increase in wind speed is more strongly limited than the decrease. So instead of a net positive effect, as might be expected from the convexity of the power curve, it results in a small negative effect. As discussed earlier in this section, OpenFAST predicts this behaviour more abruptly, while the analytical model responds more smoothly. Interestingly, in this case the analytical model predicts a smaller magnitude of change. This is likely because, in the analytical formulation, the positive contributions more strongly compensate for the negative ones, whereas OpenFAST still simulations have additional sources of power loss due to friction and control dynamics of the turbine, compared to the baseline OpenFAST simulation.

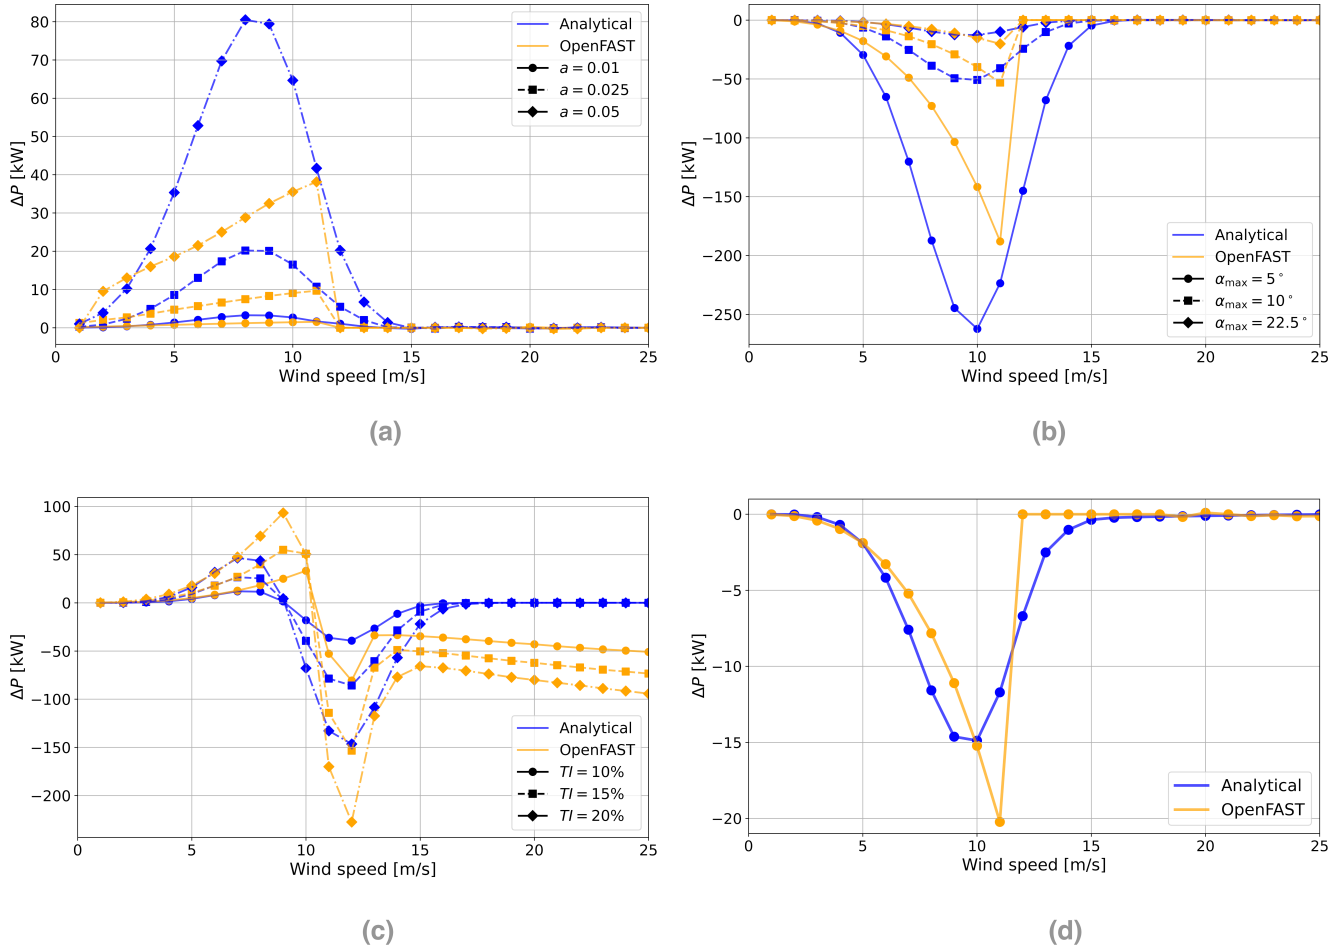

Figure 6. The difference in power production from a uniform wind profile for the four idealised vertical wind profiles. (a) Linear shear, (b) Linear veer, (c) Homogeneous turbulence intensity (TI), and (d) Logarithmic wind profile ($z_0 = 0.1 \text{ m}$).

3.3 Gotthard wind profiles

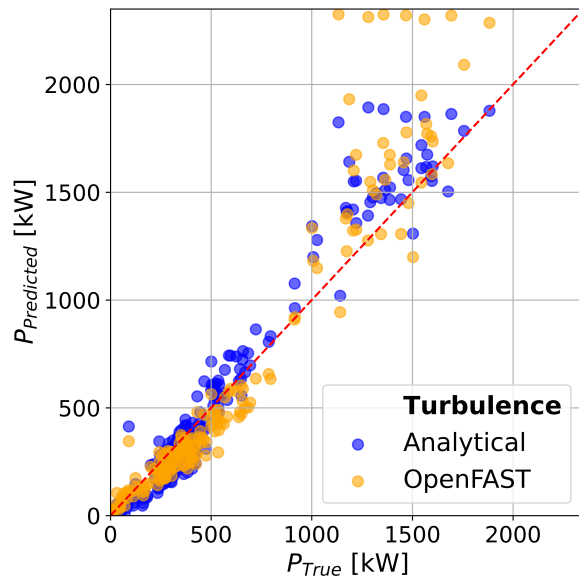

We continue by evaluating the models under real-world conditions. For this purpose we have selected ten distinct wind events at each of the five turbines in the Gotthard Wind Park. Each case spans several hours and is classified by southerly or northerly flow (Tab. 3), which are the prevailing wind regimes for this mountain pass. For each event, we make use of the Gotthard Transect Experiment dataset van Schaik et al. (2024), which includes ten Doppler wind LiDAR deployments along the pass, providing upwind vertical wind profiles from all five turbines and prevailing winds.

In Figure 7, nine of the ten cases are shown; the case of Turbine 1 with LiDAR location 9 under southerly flow is omitted. The wake effects from Turbine 2 contaminating the LiDAR wind profiles before reaching Turbine 1 requires a separate case.

410 This special case is discussed in subsection 3.4.

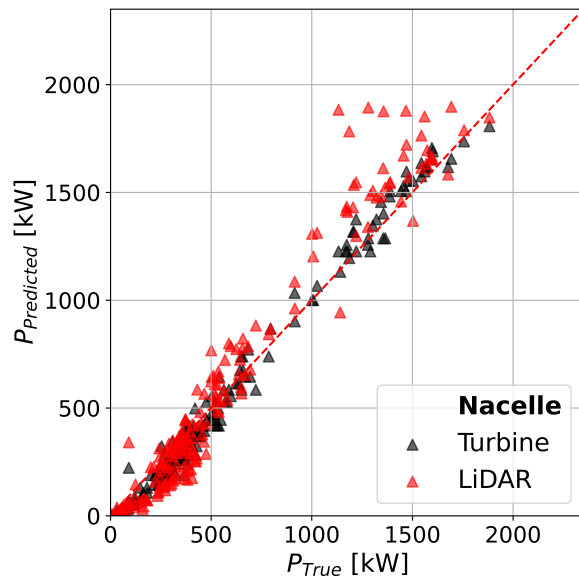

The first subfigure (Fig. 7a) compares the predicted and observed power output, with the turbulence module enabled for both models. As observed before in Fig. 6c, the turbulence improves power output until about 10 m s^{-1} , after which power production is decreased, reducing deviation from the true power in all cases. Compared to the turbulence-free case (Fig. 7b), this model version achieves much better agreement with the measured power production, particularly at high wind speeds. Here, 415 the analytical model clearly outperforms OpenFAST, which often overestimates power once the rated power of the turbine is reached. This behaviour can also be observed from the idealised wind profiles of Figure 6.

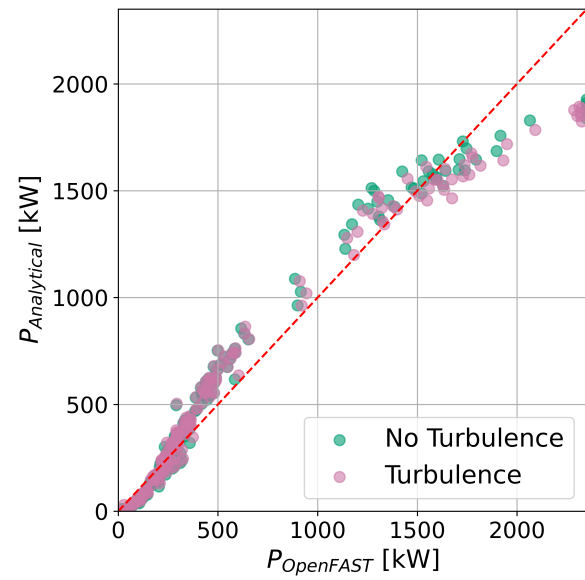

↑ (a) Model comparison including turbulence

↑ (b) Model comparison excluding turbulence

↑ (c) Standard nacelle wind power estimates

↑ (d) Analytical vs. OpenFAST cross-correlations

Figure 7. The difference in power production from a uniform wind profile for the four idealised vertical wind profiles. (a) Comparison incl. turbulence and (b) excl. turbulence. (c) Standard nacelle power estimates and (d) Model cross-correlations.

In Figure 7.d, the cross-correlation between the analytical and OpenFAST models are shown. A systematic pattern can be observed here. Firstly, at very low wind speeds, OpenFAST generates power earlier because it lacks a defined cut-in wind speed – a known unrealistic feature of the software. Secondly, in the intermediate region, the analytical model produces more power due to the stronger curvature of the power curve (Fig.5b). Finally, at higher wind speeds, OpenFAST diverges again to greater power predictions, reflecting its unrealistic post-rated behaviour. Notably, the inclusion of turbulence only has a significant impact near rated power as the power curve flattens afterwards.

To connect these findings of the power prediction models to the IEC standard methods, the third subfigure (Fig. 7) shows predictions based on nacelle-height wind speed alone. The trivial case is the turbine nacelle measurement itself (black), which unsurprisingly correlates well with true power since it is effectively calibrated against it. Still, small deviations indicate the importance of vertical variations in the inflow. More striking is the performance of the LiDAR-based nacelle-height estimations (red), which effectively serve as the IEC-standard extrapolation method. In this case, we have data available at the nacelle-height, but the IEC standard only allows for measurements from up to two-thirds of hub-height to be extrapolated for this purpose. When considering the variety of the wind profiles measured by the LiDAR on the Gotthard pass, it becomes immediately evident that there is no single surface roughness that can be assigned to this site to perform such an extrapolation. We therefore remain at the best possible case for the IEC standard by taking the LiDAR range gate closest to the elevation of the nacelle. Relative to the IEC standard approach, the analytical model reports several improvements with the inclusion of the vertical wind profiles.

Table 3. Specification and error statistics of the ten Gotthard case study sites

Case study site			LiDAR - Turbine	Number of	Bias from measured power [kW]			
Turbine	LiDAR	Wind direction	Distance	Wind profiles	Analytical	An. No-turb.	OpenFAST	IEC Standard
T1	L9	Northerly	207m	25	-13.7	-26.4	-50.2	-25.6
T1	L9	Southerly		25	-242.9*	-267.9*	-468.7	-555.5
T2	L5	Northerly	278m	25	223.7	256.6	412.0	254.8
T2	L6	Southerly		25	-20.9	-25.2	-10.6	-26.0
T3	L10	Northerly	116m	6	-32.9	-46.4	-79.6	-55.5
T3	L10	Southerly		25	-27.8	-37.4	17.2	-39.1
T4	L4	Northerly	156m	25	130.9	158.2	154.5	141.9
T4	L4	Southerly		25	-13.1	-26.4	-53.9	-20.0
T5	L7	Northerly	114m	25	67.8	64.7	-86.8	103.0
T5	L7	Southerly		25	-105.9	-121.6	-71.9	-133.7
* Corrected for wake effects				RMSE [kW]	140.3	150.5	215.7	153.8
				MAE [kW]	95.0	103.5	121.0	108.1
				R ²	0.911	0.897	0.794	0.893

As shown in Table 3, the wind power bias reduction per site relative to the IEC standard ranges from 8.6% to 46.4% depending on site complexity, with a mean bias reduction of $25.4 \pm 13.0\%$. This improvement directly translates to a more accurate prediction of turbine power production: the analytical model yields production estimates that are on average $5.4 \pm 3.8\%$ closer to observed values. Across the sites, this corresponds to improvements ranging from 0.86% to 14.1%. For the Gotthard Pass Enercon E-92 turbines, this equates to an average of 23.7 MWh per turbine closer to the true annual energy production. In terms of statistical error metrics, the analytical model reduces the RMSE by 8.8%, and the MAE by 12.2% compared to the IEC standard. However, the OpenFAST power predictions are consistently worse than the LiDAR nacelle-height wind speed method. This discrepancy can be singlehandedly attributed to the different wind turbine used in the simulations, as the proprietary aerodynamic specifications of the Enercon E92 prevent its implementation in OpenFAST. Instead, the open-source WindPACT 3.0 MW turbine had to be employed and scaled, introducing systematic differences that affect the comparability of results.

In these OpenFAST simulations of the Gotthard wind profiles, the *USRVKM* turbulence mode in TurbSim was used, providing vertical turbulence variations and the ability to specify eddy length scales, unlike the *IECKAI* mode used for the idealised profiles. Sensitivity tests across a range of turbulence intensities and eddy scales showed only minor effects on power predictions, primarily at high wind speeds. Given that the analytical model already demonstrates superior performance, the standard *USRVKM* settings were retained.

450 Overall, the results show that while nacelle-height extrapolation can provide reasonable fits, the analytical model generalises significantly better for complex terrain site assessments. Including turbulence further sharpens its predictive skill, particularly at high wind speeds, while retaining negligible computational cost compared to OpenFAST.

3.4 Wake filtering

455 In Figure 8a, the original LiDAR wind measurements are shown in orange, together with a subset of selected points outside the wake-contaminated region. From the analysis of wake direction and extent, this case was identified as the only instance where either the LiDAR or the turbine is affected by a wake. Specifically, for Turbine 1 and LiDAR location 9 under southerly wind conditions, the wake from Turbine 2 intersects the LiDAR beam but consistently bypasses Turbine 1. As a result, the LiDAR profile misrepresents the true inflow conditions of the turbine.

460 The error bars of both the orange and green profiles, as well as the shaded blue region, represent the standard deviation of the wind speed, during the 10 min time window in which complete wind profiles are measured every 5 seconds. After wake filtering, the resulting profile (blue) behaves much more consistently as if no wake was present, which is also observed by the reduced turbulence intensity, also interpolated by the Taylor expansion.

The effect on power predictions due to the filtering of the wake is shown in Figure 8b. The unfiltered case, with analytical and OpenFAST predictions in blue and orange respectively, substantially underestimates the measured turbine power. After 465 applying the wake filter, the analytical results align much more closely with the actual turbine production. Quantitatively, the RMSE decreases from 515.8 kW to 242.9 kW , which is a reduction of 53%, while the bias improves from 58% to -215.3 kW . The only trade-off is a slight decrease in correlation, from 0.55 to 0.50, indicating that the effectiveness of the wake correction varies between individual profiles. This is to be expected as the procedure simply removes a standard range of wind measurements where the wake is expected based on the height of the swept area of Turbine 2 with respect to the elevation of the 470 LiDAR. In some cases, particularly when the wind field contains a vertical component, wake remnants may still contaminate the higher points, or the correction may overcompensate, as visible in one outlier above the 1 : 1 line.

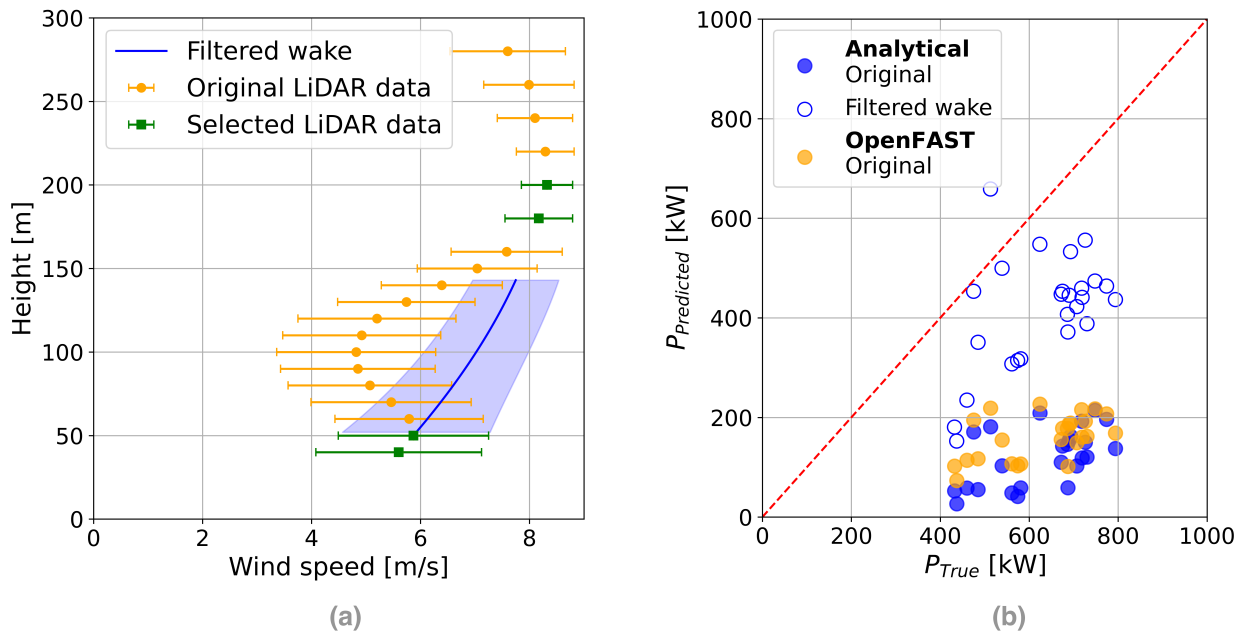

Figure 8. Wake filtering (a) wind profile and (b) power production comparison.

Despite these limitations, the approach works remarkably well and highlights a key advantage of the analytical model: it can be applied flexibly to almost any kind of input data. Whether only two measurement levels are available or a densely resolved LiDAR profile, the Taylor expansion method adapts naturally. This stands in stark contrast to the OpenFAST method which cannot directly accommodate such filtering. Importantly, the method is also turbine-independent: even before a specific turbine type is selected, a single LiDAR deployment can provide accurate wind energy assessments for any size turbine. Furthermore, wake-filtered profiles can be particularly valuable in cases such as wind farm expansions, where wake contamination is unavoidable, yet filtering offers a practical way to recover representative inflow profiles such as in off-shore applications where one can expect the unaffected wind profile to be similar within a few kilometres from the LiDAR site.

3.5 Robustness and Sensitivity Tests

In addition to the core results, several supplementary tests were conducted to evaluate the robustness of the analytical model. First, the sensitivity to air density was investigated using OpenFAST simulations across a range of values representative for wind parks at different elevations. The analytical model was found to be well behaved across the full range, with no need to adjust the shape of the $C_p(v)$ curve, confirming its transferability to sites at different elevations.

Secondly, we tested the impact of using alternative turbine power curves. When replacing the Enercon E-92 curve with the WindPACT 3.0MW reference turbine, the agreement between the analytical model and OpenFAST became closer, although this improvement was primarily due to a degradation of the analytical model rather than an enhancement of OpenFAST. This

illustrates that the framework can be applied to arbitrary power curves, as the analytical approximation in Eq. 7 is flexible and well behaved.

490 Finally, we assessed the impact of averaging on estimates of $\overline{v^3}$ by re-averaging the 1 s LiDAR wind-speed data to a range of averaging windows (1, 2, 5, 10, 20, and 30 minutes, and 1 hour). For otherwise comparable conditions, the resulting values of $\overline{v^3}$ differed by up to 4% relative to estimates based on \overline{v} , illustrating the sensitivity of power-related metrics to the chosen averaging interval. Since 10-minute averages remain the standard in wind-energy applications, we adopt them here, while noting that this choice introduces a small but unavoidable uncertainty in the order of several percent.

495 Together, these tests demonstrate that the analytical model is robust to variations in air density and turbine power curves, and that averaging effects introduce only a limited and unavoidable contribution to the overall error budget.

4 Conclusions

In this study, we introduced and validated a new analytical framework for predicting wind turbine power production that explicitly accounts for vertical wind profile variability through an integral formulation. By combining Taylor expansions of the inflow with an analytical representation of the turbine power curve, the model provides a clearly improved alternative to the IEC standard for wind energy assessment based on a single nacelle-height wind measurement. Furthermore, it provides a flexible alternative to costly numerical simulation of wind turbine aerodynamics.

The results show that the primary discrepancies between the analytical model and OpenFAST can be attributed to differences in the turbine power curves. While the analytical model was configured for the Enercon E-92 turbine, reflecting the real-world LiDAR measurements at the Gotthard Pass, OpenFAST required the use of the WindPACT 3.0MW reference turbine. The unusual $C_p(v)$ curve of the latter, including the absence of realistic cut-in and cut-out wind speeds, amplified differences in the response to vertical wind profile variations. This effect is best represented by considering the curvature ($\frac{d^2P}{dv^2}$) of the power curve, which confirms the mechanism and provided an explanation for the observed discrepancies in the predicted power of the turbines.

510 When applying the analytical model to idealised wind profiles, such as shear -, veer-, logarithmic wind profiles, as well as homogeneous turbulence intensities, we demonstrated that the analytical formulation produces smoother and more physically consistent power predictions compared to OpenFAST. These differences are likely driven by the different power curves.

This same effect is also visible in the real Gotthard LiDAR profiles, which provided a direct validation against real-world inflow conditions. The vertical wind profiles at this alpine site are strongly shaped by shear, veer, and turbulence, and represent a complex but highly relevant test case for wind energy production. Compared to OpenFAST, the analytical model showed smoother and more consistent responses to these profiles, reflecting the more regular curvature of the Enercon E-92 power curve used in its formulation. Resulting in remarkably high goodness of fit of $R^2 = 0.911$, with typical bias reduction of $25.4 \pm 13.0\%$ which corresponds to an annual average of $23.7 MWh$ per turbine (Enercon E92 2.35MW) closer to the true production power for this highly complex Alpine site.

520 The wake filtering analysis further illustrated the strength of the analytical approach by means of its flexibility: By excluding the portion of the LiDAR profile affected by a turbine wake, the analytical model predictions were brought significantly closer to the measured power, reducing the RMSE and Bias by more than 50%, significantly closer to the typical skill of the other cases. Although, the slight decrease in correlation suggests that this method does not work as effectively on every wind profile due to leaking over wake effects. Further work should consult the plethora of literature available on wake detection, which will
525 likely be the remedy to this rather straight-forward problem that is outside of the scope of this work.

Further robustness and sensitivity tests confirmed that the analytical framework performs consistently across a range of air densities representative of all elevations, and that the method can be applied to arbitrary power curves thanks to the analytical approximation of Eq. 7. Furthermore, we have conducted tests on the sensitivity of the 10-minute averaging window which has become state-of-the-art in the wind energy industry and conclude that this does introduce a small additional, and probably
530 unavoidable, uncertainty of up to 4% in the power prediction. This effect is minor not of interest to study further given the trade-off with turbulence statistics.

In summary, the analytical model developed here applies a simple physical interpretation of vertical variations in the wind in a computationally efficient and highly flexible tool for assessing turbine power production under vertically varying wind conditions. It captures the essential mechanisms behind power output variations, explains discrepancies with simulation-based
535 models through power curve curvature, and can be robustly applied across sites, turbines and measurement configurations. Beyond its application in the Swiss Alps with the Gotthard Pass case study, the model offers a new pathway to bridge measurements that we think should be considered to be amended in today's wind energy assessment standards, as it is low impact due to our open-source code for the tool, and the trend of using LiDAR in site selection for wind parks which already include this additional information of vertical wind profiles. We particularly want to highlight the value in the practicality of use in the ma-
540 jority of cases where wind turbine aerodynamic specifications are proprietary. Something that more sophisticated simulations and other state-of-the-art tools require, which is completely avoidable by this method.

Code and data availability. All data is publicly available via the Zenodo database van Schaik et al. (2025a) doi: <https://doi.org/10.5281/zenodo.17804408>. With the single exception of the Gotthard Wind Park Turbine Power data, which was used under NDA. This data may be made available under request to the authors for scientific purposes only. The Zenodo database additionally includes open source code for the
545 analytical power prediction tool as well as example codes and instructions to operate the software.

Appendix A: Analytical power equation derivation

From Taylor series theory, a continuous function such as the wind speed profile can be approximated by a polynomial:

$$v(z) = \sum_{i=0}^N c_i z^i \quad (\text{A1})$$

The standard turbine power equation is:

$$550 \quad P(z) = \frac{1}{2} C_p(v) \rho A v(z)^3 \quad (\text{A2})$$

We integrate over the circular swept area by converting the surface integral to a 1D integral in height:

$$P = \frac{1}{2} C_p(v) \rho \int_{-R}^R 2\sqrt{R^2 - z^2} v(z)^3 dz \quad (\text{A3})$$

To integrate over the height z , we must define the cube of the wind speed that is parallel to the normal vector of the swept area:

$$555 \quad (v(z))^3 = \sum_{i,j,k}^N c_i c_j c_k z^{i+j+k} = \sum_i^N \left(c_i \sum_j^N \left(c_j \sum_k^N (c_k z^{i+j+k}) \right) \right) \quad (\text{A4})$$

Such that we can define the turbine power equation as a integral over height z .

$$P(v, z) = \frac{1}{2} C_p(v) \rho \int_{-R}^R 2\sqrt{R^2 - z^2} v(z)^3 dz \quad (\text{A5})$$

We solve this analytically by the following substitution:

$$z = R \sin(u), u = \arcsin\left(\frac{z}{R}\right), dz = R \cos(u) du \quad (\text{A6})$$

560 Such that the power equation becomes:

$$P(v, u) = \frac{1}{2} C_p(v) \rho \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} 2R \cos(u) \sqrt{R^2 - R^2 \sin^2(u)} \sum_{i,j,k}^N c_i c_j c_k R^{i+j+k} \sin^{i+j+k}(u) du \quad (\text{A7})$$

Simplifying by removing the factor 2 out of the integral, and by rearranging the square root:

$$P(v, u) = C_p(v) \rho \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} R \cos(u) \sqrt{R^2 (1 - \sin^2(u))} \sum_{i,j,k}^N c_i c_j c_k R^{i+j+k} \sin^{i+j+k}(u) du \quad (\text{A8})$$

The square root can be resolved by a trigonometric substitution to find:

$$565 \quad P(v, u) = C_p(v) \rho \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} R^2 \cos^2(u) \sum_{i,j,k}^N c_i c_j c_k R^{i+j+k} \sin^{i+j+k}(u) du \quad (\text{A9})$$

We can move the triple summation, including several constants out of the integral to simplify the integral to a purely trigonometric problem:

$$P(v, u) = C_p(v) \rho R^2 \sum_{i,j,k}^N c_i c_j c_k R^{i+j+k} \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \cos^2(u) \sin^{i+j+k}(u) du \quad (\text{A10})$$

We now focus on the integral only, by defining it as Q :

$$570 \quad P(v, u) = C_p(v) \rho R^2 \sum_{i,j,k}^N c_i c_j c_k R^{i+j+k} Q(u) \quad (\text{A11})$$

Where the substitution $Q(z)$ also replaces $i + j + k$ by a new integer m :

$$Q(u) = \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \cos^2(u) \sin^m(u) du, \quad m = i + j + k \quad (\text{A12})$$

For odd values of m , the integrand $\cos^2(u) \sin^m(u)$ is an odd function, and the integral over the symmetric interval $[-\pi/2, \pi/2]$ evaluates to 0:

$$575 \quad Q(u) = 0, \quad \text{if } m \text{ is odd.} \quad (\text{A13})$$

For even values of m , let $m = 2s$, where s is an integer. The integrand $\cos^2(u) \sin^{2s}(u)$ is an even function, and by symmetry, the integral can be simplified by doubling the range from $[0, \pi/2]$:

$$Q(u) = 2 \int_0^{\frac{\pi}{2}} \cos^2(u) \sin^{2s}(u) du, \quad \text{if } m = 2s. \quad (\text{A14})$$

We once again apply the trigonometric identity to eliminate the cosine from the integrand.

$$580 \quad Q(u) = 2 \int_0^{\frac{\pi}{2}} (1 - \sin^2(u)) \sin^{2s}(u) du, \quad \text{if } m = 2s. \quad (\text{A15})$$

We can split this integral in two relatively simple integrals:

$$Q(u) = 2 \left(\int_0^{\frac{\pi}{2}} \sin^{2s}(u) du - \int_0^{\frac{\pi}{2}} \sin^{2(s+1)}(u) du \right), \quad \text{if } m = 2s. \quad (\text{A16})$$

Which are both similar integrals as the exponent of the sine is always even. The integral of $\sin^{2s}(u)$ over the interval $[0, \pi/2]$ is given by:

$$585 \quad \int_0^{\frac{\pi}{2}} \sin^{2s}(u) du = \frac{1}{2} B\left(s + \frac{1}{2}, \frac{1}{2}\right), \quad (\text{A17})$$

where $B(x, y)$ is the Beta function. Using the relationship between the Beta and Gamma functions:

$$B(x, y) = \frac{\Gamma(x)\Gamma(y)}{\Gamma(x+y)}, \quad (\text{A18})$$

the integral can be written as:

$$\int_0^{\frac{\pi}{2}} \sin^{2s}(u) du = \frac{\sqrt{\pi}}{2} \cdot \frac{\Gamma(s + \frac{1}{2})}{\Gamma(s + 1)}. \quad (\text{A19})$$

590 Here, $\Gamma(z)$ is the Gamma function, and $\Gamma(\frac{1}{2}) = \sqrt{\pi}$.
 Such that $Q(u)$, for even values of $m = 2s$, is given by:

$$Q(u) = \sqrt{\pi} \left(\frac{\Gamma(s + \frac{1}{2})}{\Gamma(s + 1)} - \frac{\Gamma(s + \frac{3}{2})}{\Gamma(s + 2)} \right) \quad (\text{A20})$$

And the turbine power equation is given by:

$$P(v) = C_p(v) \rho R^2 \sum_{i,j,k}^N c_i c_j c_k R^m \sqrt{\pi} \left(\frac{\Gamma(s + \frac{1}{2})}{\Gamma(s + 1)} - \frac{\Gamma(s + \frac{3}{2})}{\Gamma(s + 2)} \right) \quad m = 2s = i + j + k \mid m \text{ is even} \quad (\text{A21})$$

595 Which is only a function of wind speed v again.
 The Gamma function $\Gamma(z)$, is defined by:

$$\Gamma(z) = \int_0^{\infty} t^{z-1} e^{-t} dt \quad (\text{A22})$$

For positive integers, where $z = s = m/2 = (i + j + k)/2$ (with m the sum of the three positive integers), the Gamma function simplifies as:

$$600 \quad \Gamma(m) = (m - 1)! \quad (\text{A23})$$

To evaluate the Gamma function at half-integer values, consider $z = m + \frac{1}{2}$, where m is a non-negative integer. The key idea comes from using the recursive property of the Gamma function and its relationship with the factorial for half-integer arguments.

Using the reflection formula and the recurrence relation:

$$605 \quad \Gamma\left(\frac{1}{2}\right) = \sqrt{\pi} \quad (\text{A24})$$

and for higher half-integer values, you apply the recurrence relation $\Gamma(z + 1) = z\Gamma(z)$ repeatedly. For example:

$$\Gamma\left(\frac{3}{2}\right) = \frac{1}{2}\Gamma\left(\frac{1}{2}\right) = \frac{1}{2}\sqrt{\pi} \quad (\text{A25})$$

$$\Gamma\left(\frac{5}{2}\right) = \frac{3}{2}\Gamma\left(\frac{3}{2}\right) = \frac{3}{2} \cdot \frac{1}{2}\sqrt{\pi} = \frac{3}{4}\sqrt{\pi} \quad (\text{A26})$$

$$\Gamma\left(\frac{7}{2}\right) = \frac{5}{2}\Gamma\left(\frac{5}{2}\right) = \frac{5}{2} \cdot \frac{3}{4}\sqrt{\pi} = \frac{15}{8}\sqrt{\pi} \quad (\text{A27})$$

610 The general result for half-integer values of $\Gamma\left(n + \frac{1}{2}\right)$ (where n is a non-negative integer) is:

$$\Gamma\left(s + \frac{1}{2}\right) = \frac{(2s)!}{4^s s!} \sqrt{\pi} \quad (\text{A28})$$

Thus, the Gamma function evaluated at half-integers $s + \frac{1}{2}$ is a product of a factorial expression, $\sqrt{\pi}$, and powers of 4.

Such that finally we can replace the full integer Gamma functions

$$P(v) = C_p(v) \rho \sqrt{\pi} R^2 \sum_{i,j,k} c_i c_j c_k R^m \left(\frac{\Gamma(s + \frac{1}{2})}{s!} - \frac{\Gamma(s + \frac{3}{2})}{(s+1)!} \right), \quad m = 2s = i + j + k \mid m \text{ is even} \quad (\text{A29})$$

615 We apply the recurrence relation on the $\Gamma(s + \frac{3}{2})$:

$$P(v) = C_p(v) \rho \sqrt{\pi} R^2 \sum_{i,j,k} c_i c_j c_k R^m \left(\frac{\Gamma(s + \frac{1}{2})}{s!} - \frac{(s + \frac{1}{2}) \Gamma(s + \frac{1}{2})}{(s+1)!} \right), \quad m = 2s = i + j + k \mid m \text{ is even} \quad (\text{A30})$$

We rearrange to a single Gamma function:

$$P(v) = C_p(v) \rho \sqrt{\pi} R^2 \sum_{i,j,k} c_i c_j c_k R^m \left(\frac{(s+1)! - s!(s + \frac{1}{2})}{s!(s+1)!} \Gamma\left(s + \frac{1}{2}\right) \right), \quad m = 2s = i + j + k \mid m \text{ is even} \quad (\text{A31})$$

Reduce the $(s+1)!$ to $s!(s+1)$:

$$620 \quad P(v) = C_p(v) \rho \sqrt{\pi} R^2 \sum_{i,j,k} c_i c_j c_k R^m \left(\frac{s!(s+1) - s!(s + \frac{1}{2})}{s!(s+1)!} \Gamma\left(s + \frac{1}{2}\right) \right), \quad m = 2s = i + j + k \mid m \text{ is even} \quad (\text{A32})$$

Which cancels out the $s!$:

$$P(v) = C_p(v) \rho \sqrt{\pi} R^2 \sum_{i,j,k} c_i c_j c_k R^m \left(\frac{1}{2} \frac{1}{(s+1)!} \Gamma\left(s + \frac{1}{2}\right) \right), \quad m = 2s = i + j + k \mid m \text{ is even} \quad (\text{A33})$$

We finally use the general result for half-integer values of the Gamme function to find:

$$P(v) = C_p(v) \rho \pi R^2 \sum_{i,j,k} c_i c_j c_k R^m \frac{1}{2} \frac{1}{(s+1)!} \frac{(2s)!}{4^s s!}, \quad m = 2s = i + j + k \mid m \text{ is even} \quad (\text{A34})$$

625 Where the $\sqrt{\pi}$ reunites with the other $\sqrt{\pi}$ to arrange $A = \pi R^2$ which obviously refers to the swept area of the blade A . We also replace s with $m/2$:

$$P(v) = C_p(v) \rho \pi R^2 \sum_{i,j,k}^N c_i c_j c_k R^m \frac{1}{2} \frac{1}{(\frac{m}{2} + 1)!} \frac{m!}{2^m \frac{m}{2}!}, \quad m = i + j + k \mid m \text{ is even} \quad (\text{A35})$$

Some final mathematical book-keeping where the half is moved to the front and πR^2 is combined to reflect the regular expression of the power equation, and by rearranging the factorials and exponents of 2, results in

$$630 \quad P(v) = \frac{1}{2} C_p(v) \rho A \sum_{i,j,k=0}^N c_i c_j c_k R^m \frac{m!}{2^m (\frac{m}{2}!)^2 (\frac{m}{2} + 1)!}, \quad m = i + j + k \mid m \text{ is even} \quad (\text{A36})$$

Which brings us back to the very familiar structure of the turbine power equation 1.

Proving that there exists a general analytical solution for the turbine power output for any continuous function $v(h)$ as an inflow of a wind turbine.

This large fraction of factorials only has to be calculated for even values of m and can be found for $m \leq 10$ in Table A1:

Table A1. Look-up table for values of m for the large factorial fraction.

m	fraction
0	1
2	$\frac{1}{4}$
4	$\frac{1}{8}$
6	$\frac{5}{64}$
8	$\frac{7}{128}$
10	$\frac{21}{512}$

635 A1 Verification: Units

As verification of this derivation, we can check the units of this equation:

$$P \rightarrow [W = N m s^{-1} = kg m^2 s^{-3}], \quad (A1)$$

$$C_p \rightarrow [1], \quad (A2)$$

$$\rho \rightarrow [kg m^{-3}], \quad (A3)$$

$$640 \quad R^2 \rightarrow [m^2], \quad (A4)$$

$$c_i, c_j, c_k \rightarrow [m^{1-i} s^{-1}], [m^{1-j} s^{-1}], [m^{1-k} s^{-1}], \quad (A5)$$

$$R^{i+j+k} \rightarrow [m^{i+j+k}]. \quad (A6)$$

Such that:

$$[kg m^2 s^{-3}] = [1] \cdot [kg m^{-3}] \cdot [m^2] \cdot [m^{1-i} s^{-1}] \cdot [m^{1-j} s^{-1}] \cdot [m^{1-k} s^{-1}] \cdot [m^{i+j+k}] \quad (A7)$$

645 Which indeed agrees.

A2 Verification: Linear Shear

Additionally, we can verify whether this is correct by taking a linear equation for $v(z) = \bar{v} + az = c_0 + c_1 z$, such that $N = 1$:

$$P(v) = \frac{1}{2} C_p(v) \rho A \left(c_0^3 + 3c_0 c_1^2 R^2 \cdot \frac{1}{4} \right) = \frac{1}{2} C_p(v) \rho A \left(\bar{v}^3 + \frac{3}{4} R^2 a^2 \bar{v} \right) \quad (A8)$$

Which agrees with regular integration of this function.

650 A3 Verification: Linear Veer

Similarly, let us verify the veer equation $v(z) = \bar{v} \cos(\alpha_{max} \frac{z}{R})$. By taylor expansion:

$$v(z) = \bar{v} - \frac{\bar{v} \alpha_{max}^2}{2R^2} z^2 + \mathcal{O}(h^4) = c_0 + c_2 z^2 \quad (A9)$$

with $c_0 = \bar{v}$, $c_1 = 0$, and $c_2 = \bar{v} \frac{\alpha_{\max}^2}{2R^2}$, where the h^4 and higher terms are discarded.

$$P(v) = \frac{1}{2} C_p(v) \rho A \left(c_0^3 + 3c_0^2 c_2 R^2 \cdot \frac{1}{4} + 3c_0 c_2^2 R^4 \cdot \frac{1}{8} + c_2^3 R^6 \cdot \frac{5}{64} \right) \approx \frac{1}{2} C_p(v) \rho A \bar{v}^3 \left(1 - \frac{3}{8} \frac{\alpha_{\max}^2}{R^2} \right) \quad (\text{A10})$$

655 Where we also discarded the R^4 and R^6 term, which agrees again with the regular integration method.
